At the close of my criticism, I have but two more suggestions to offer, the more universal instruction in public schools in physical exercises, breathing exercises especially, and lessons how not to become consumptive and lessons on hygiene in general; and lastly, the creation of a National Board of Health, the equivalent of the "Deutsche Reichsgesundheitsamt" of Berlin or the "Direction d'Hygiène Publique" of Paris with its "Comité Consultatif" under the direction of the Minister of the Interior. Such an institution, with its seat at Washington, could give uniform hygienic laws, and being counseled by the most competent in the profession, would aid us best in our struggle against this most deadly of all diseases. By requiring health officers all over the United States to take a course in practical hygiene, it would give a great impulse to sanitary science. We might then hope for effective work, and for thorough and feasible methods to combat tuberculosis in man and beast through the length and breadth of our beautiful land.

955 Madison Avenue.

THE PRESENT ATTITUDE OF SANITARIANS AND BOARDS OF HEALTH IN REGARD TO PULMONARY TUBERCULOSIS.

Presented in the Section on State Medicine, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY BENJAMIN LEE, A.M., M.D., Ph.D.
PHILADELPHIA, PA.

The question of the communicability of pulmonary tuberculosis, consumption of the lungs or pulmonary phthisis, has long passed the boundary of discussion with the great mass of the medical profession.

Here and there an individual who places a very high estimate on his reputation for consistency persists in attempting to controvert it, because it was not the belief in which he was educated, and because he opposed it when, in consequence of the researches of the bacteriologic investigators, it was first resuscitated. But, in the main, the consensus of professional opinion strongly supports it. Those who take an intelligent interest in the promotion of public health and have thus been led to give the subject more especial attention are even more thoroughly convinced of the fact than are those who confine their studies strictly to therapeutics and the daily routine of practice; while those whose official positions make it their duty to do all in their power to extinguish disease, diminish the death-rate, and promote longevity, entertain convictions so positive as to lead them to believe in the possibility of the adoption of measures which shall restrict the spread of the disease and thus add an incalculable number of years to the aggregate of human life. Holding such convictions they would be false to their consciences and to their official oaths did they hesitate to formulate such measures and to urge their adoption on the law-making power. Such efforts of course provoke opposition, and the form which that opposition takes is that of attempting to create a public sentiment averse to the adoption of any restrictions whatever by misrepresenting the character of the regulations proposed and magnifying the discomforts and annoyances which would result from their enforcement. Even if the proposed measures were as unwise and as rigorous as they have been distorted into appearing, I doubt if any one is so bold as to deny that they should be adopted, if there be reasonable ground to hope that by such means, and by no others, could the terrible ravages of this affection be materially checked. Fortunately, however, these are not the views of sanitarians and of boards of health.

The more carefully the mode of propagation of the disease is studied the simpler becomes the problem of its legal restriction. No Board of Health, so far as I know, has promulgated the dogma attributed to those who are in favor of giving the knowledge which we now possess a legal expression that shall make it of use to the community, that "these unfortunates should be isolated from family or friends and treated as creatures disseminating a contagious disease, like smallpox, yellow fever, scarlet fever or diphtheria." What then can sanitary authorities do, and what do they propose to do, to diminish the prevalence of consumption and therefore all forms of tuberculosis, whether attacking the pulmonary or other tissue of the body?

1. They can and should formally and publicly announce their belief that, after a certain stage of tubercular phthisis has been reached, namely, that of softening, breaking down or suppuration, the individual affected becomes a source of danger to those immediately surrounding him and to the public, and of infection of material objects, such as walls, bedding and furniture.

2. They can and should formulate and disseminate as widely as possible, simple, concise instructions as to the precautions which such patients should themselves take in order to prevent or minimize these dangers.

3. They can and should have a knowledge of every case of consumption which has reached the stage referred to, existing within the limits of their respective jurisdictions and, as this information can be obtained in no other way, they can and should require physicians to report to them all such cases occurring in their practice, whether privately or in public institutions, within a certain definite time after the diagnosis had been established.

4. They can and should offer to aid the physician in any case where he is doubt, by affording facilities for the bacteriologic diagnosis of the disease.

5. They can and should insist on the disinfection, by such means as they deem most effective, of every apartment from which such a patient has been removed, whether by death or otherwise.

6. They can and should insist on the disinfection of berths and state rooms in public conveyances, whether on land or water, in which such patients have passed one or more nights.

7. They can and should in every possible way disseminate information as to the dangers arising from the habit of spitting in public places and especially on the floors of public conveyances, whether on land or water.

8. They can and should formulate municipal ordinances and State laws for the restriction of this dangerous habit and urge the passage of the same.

The following are copies of resolutions and an ordinance framed with this object, by the Board of Health of the City of Philadelphia, and presented to the councils but not yet adopted:

> WHEREAS, The habit of spitting in frequented public places, particularly when such places are enclosed, is not only uncleanly and unnecessary, but prejudicial to health; and
>
> WHEREAS, It is proved that certain diseases, as consumption, are mostly propagated by dried expectorations, and for this reason alone should be condemned; it is therefore
>
> *Resolved*, That city councils be respectfully requested to coöperate with the Board of Health in their endeavors to restrict, if not prevent, this pernicious habit, and they are hereby earnestly solicited to pass the following ordinance, not only to promote cleanliness, but to safeguard the public health:
>
> An Ordinance Forbidding Spitting in Public Buildings and Passenger Railway Cars.
>
> WHEREAS, Spitting in public building and passenger railway cars has been declared by Boards of Health of different cities in the United States to be prejudicial to the health of the people who visit such buildings or ride in such cars; and
>
> WHEREAS, This practice is not only unhealthy, but uncleanly, offensive and filthy, and injurious to wearing apparel, especially of women, and therefore, a common nuisance; therefore
>
> SECTION 1. The Select and Common Councils of the City of Philadelphia do ordain: That spitting upon the floors of public buildings and of passenger railway-cars is hereby declared to be a nuisance and prejudicial to health, and is hereby prohibited under a penalty of $5 for each and every offense, to be recovered as penalties of like amount are by law recoverable."

The value of such an ordinance as an education would be even greater than that which it would possess in the direct restriction of disease.

9. They can and should do all in their power to promote the establishment of hospitals and sanatoria for consumptives both by State and municipal authorities, with large provision for such persons as are unable for pecunary reasons, to avail themselves of such refuges already established by private enterprise. This measure should be urged not on the score of humanity or charity, but simply as the most effective means of protecting the public health, so far as the spread of tuberculosis is concerned, that has yet been devised. There would be no necessity for dragging these unfortunates from their families and homes to place them in such institutions. There are multitudes waiting for just such opportunities, who would be only too glad to embrace them.

10. They can and should do all in their power to promote such legislation as would ensure the systematic inspection of dairies and dairy-farms, in order that all cattle giving evidence in any way of being affected with tuberculosis may be at once isolated and the quarters which they occupied thoroughly disinfected.

It will be gathered from this hasty résumé of the responsibilities which health authorities feel to be resting upon them in this regard, that it is by no means contemplated to use the same precautions and restrictions for consumption, such as placarding or guarding houses, and isolating patients, as are in force for smallpox and diphtheria.

Section 225, of the Sanitary Code of the City of New York adopted in January of the present year, may be fairly taken as an exponent of the general feeling of sanitary officials on this subject. It read as follows:

> That pulmonary tuberculosis is hereby declared to be an infectious and communicable disease dangerous to the public health. It shall be the duty of every physician in this city to report to the Sanitary Bureau in writing, the name, age, sex, occupation and address of every person having such disease who has been attended by or who has come under the observation of such physician for the first time, within one week of such time. It shall also be the duty of the commissioners or managers or the principal, superintendent or physician of such and every public or private institution c [illegible] in this city, to report to the Sanitary Bur[illegible] use such report to be made by some [illegible] on, the name age, sex, occupation [illegible] on

afflicted with this disease who is in their care or has come under their observation within one week of such time. It shall be the duty of every person sick with this disease and of the authorities of public and private institutions or dispensaries, to observe and enforce all the sanitary rules and regulations of the Board of Health for preventing the spread of pulmonary tuberculosis.

(L. S) Charles G. Wilson, President.
Emmons Clark, Secretary.

It will be observed that this regulation limits itself to declaring that pulmonary tuberculosis is an infectious and communicable disease, to requiring its occurrence to be reported, and to insisting on the observation of the precautions of the Board for preventing the spread *not of the acute contagious diseases*, but of this one particular disease.

The nature of these precautions may be gathered from the following circular of the Board, entitled "Information for Consumptives and Those Living with Them."

HEALTH DEPARTMENT, CRIMINAL COURT BUILDING, CENTER, WHITE, ELM AND FRANKLIN STREETS, NEW YORK.

Consumption is a disease which can be taken from others and is not simply caused by colds. A cold may make it easier to take the disease. It is usually caused by germs which enter the body with the air breathed. The matter which consumptives cough or spit up contains the germs in great numbers; frequently millions are discharged in a single day. This matter, spit upon the floor, wall or elsewhere, is apt to dry, become pulverized and float in the air as dust. The dust contains the germs, and thus they enter the body with the air breathed. The breath of a consumptive dees not contain the germs and will not produce the disease. A well person catches the disease from the consumptive only by in some way taking in the matter coughed up by the consumptive.

Consumption can often be cured if its nature is recognized early and proper means are taken for its treatment. *In a majority of cases it is not a fatal disease.*

It is not dangerous for other persons to live with a consumptive, if the matter coughed up by the consumptive is at once destroyed. This matter should not be spit upon the floor, carpet, stove, wall, or anywhere except into a cup kept for the purpose. The cup should contain water so that the matter may not dry, and should be emptied into the closet at least twice a day and carefully washed with hot water. Great care should be taken by a consumptive that his hands, face and clothing do not become soiled with the matter coughed up. If they do become soiled they should be at once washed with hot soap and water. When consumptives are away from home, the matter coughed up may be received on cloths, which should be at once burned on returning home. If handkerchiefs are used (worthless cloths which can be burned are far better), they should be boiled in water by themselves before being washed.

It is better for a consumptive to sleep alone, and his bedclothing and personal clothing should be boiled and washed separately from the clothing belonging to other people.

Whenever a person is thought to be suffering from consumption, the name and address should be at once sent to the Health Department, on a postal card with a statement of the facts. A medical inspector from the Health Department will then call and examine the person to see if he has consumption, providing he has no physician, and, if necessary, will give proper directions to prevent others from catching the disease.

Frequently a person suffering from consumption may not only do his usual work without giving the disease to others, but may also get well if the matter coughed up is properly destroyed.

Rooms that have been occupied by consumptives should be thoroughly cleaned, scrubbed, whitewashed, painted, or papered before they are again occupied. Carpets, rugs, bedding, etc., from rooms which have been occupied by consumptives, should be disinfected. The Health Department should be notified, when they will be sent for, disinfected and returned to the owner free of charge, or, if he so desires, they will be destroyed.

By order of the Board of Health,
Charles G. Wilson, President.
Emmons Clark, Secretary.

The State Board of Health of Pennsylvania has contented itself, so far, with adopting a resolution advising all local boards to place tuberculosis on the list of communicable diseases, to be reported, and issuing a precautionary circular for the information of local boards, and also of those who may be suffering from the disease. By such sufferers these circulars are, as a rule, gratefully received. This circular is No. 28, entitled "Precautions Against Consumption" and treats of the history and nature of the disease; how the disease is spread or acquired; precautions with regard to cattle; precautions to be observed by the patient; disease germs; precautions to be taken in the sick-room; precautions to be taken after the death of the patient; and precautions to be taken by the proprietors of public houses and public conveyances.

THE ANTITOXIC AND BACTERICIDAL PROPERTIES OF THE SERUM OF HORSES TREATED WITH KOCH'S NEW TUBERCULIN.

Read at the Twenty-third Annual Meeting of the Mississippi Valley Medical Association, held at Louisville, Ky., Oct. 5-8, 1897.

BY CARL FISCH, M.D.
ST. LOUIS, MO.

All attempts at establishing a serotherapy in tuberculosis have hitherto failed, that means, if we understand by serotherapy a specific prophylactic or curative treatment, like the one established in diphtheria or tetanus. So decided and pronounced has this failure been that in the mind of many observers a strong prejudice has been created, a prejudice that appears the more justifiable since commercialism has not hesitated in exploiting so promising a field. We would however be very hasty in drawing from these failures the conclusion that serotherapy in consumption is not a thing to be hoped for, as has been done by many writers. We can not be too chary in making final statements, a postulate that at this very time emphasizes itself with particular weight by the discovery made by Kitasato of an antitoxic typhoid serum. Has it not been for some time past one of our axioms, that in typhoid and cholera only bactericidal and no antitoxic properties were developed? The less we try to encase new ideas, and serotherapy is a new idea, in the forms of old conceptions, the less frequently we will have to retrace our steps. No metewand has as yet been discovered to point out the limits and boundaries of this new idea; whoever talks about the limits of serotherapy confesses that he does not or will not understand its origin.

For these very reasons it is an unpromising task to foretell by logic reasoning, whether or to what degree serum treatment will influence tuberculosis. Nobody ever expected that it would bring about a *restitutio ad integrum* in advanced cases, or redress the ravages of septic complications. It is certainly absolutely erroneous to insist that the anatomo-pathologic phenomena of pure tuberculosis, are not indicative of a toxic process which might be amenable to antitoxic impressions. Such intoxication exists from the very first hour, I might say, of the beginning of tuberculous infection, a fact that is not only evidenced by histologic changes, but that can also be proven by physiologic reactions. To say that the early tuberculous changes are simply of an inflammatory character expresses only a morphologic phenomenon. Physiologically they are as pronouncedly caused by bacterial toxins as are any other bacterial intoxications. It is true this toxic inflammatory process is little noticeable in its early stages and becomes mostly chronic, gradually undermining the vital vigor and leading to fatal loss of substance or secondary infections (in fact, very few persons die of chronic tuberculosis), but in this very chronicity the battle waged between the human organism and the array of bacterial toxins expresses itself; very often the former remains victorious perhaps in a majority of cases. In our language such a victory means immunization although only for the time being.

It is not here the place to enter more fully into these exceedingly interesting questions. I had to touch upon them because it has ever and again been contested that theoretically there were no prospects for serotherapy in this disease. Valuable remarks regarding this topic may be found in an able paper of Joseph McFarland.[1]

But we would be wrong if we attributed this reserve to well conceived and understood pathologic considerations alone; behind them there lurks a preconceived idea of self-limitedness; and above all a mysterious predisposition for the disease. This hereditary predisposition would be well worth to be looked into a little more thoroughly; I can not do it here, and must confine myself to the statement that a scientific base for the tubercular predisposition still is wanting.[2]

Not mentioning those attempts at putting forth an antitubercular serum that were only prompted by mercenary motives, the number of honest workers in this field is quite large. Since Richet and Hericourt first began their experiments an enormous amount of persevering and unselfish work has been done. I will only mention the names of Courmont, Babes, Niemann, Maragliano, Schweinitz, etc. Admitting that there are considerable differences between the several methods employed by these investigators, entering into which would lead us too far here, there is one source of error common to all, that is the material used for immunizing the animals which were used for the purpose. If we look over the laborious experiments of Koch to establish immunity by means of tubercle bacilli or of their products, we find that the chief difficulty was to cause the tubercle bacilli to be absorbed by the tissues or to chemically so act on the bacilli that their immunizing ingredients were contained in a fluid extract. The peculiar morphologic and chemic constitution of the tubercle bacilli made, indeed, all these experiments unsuccessful. Koch had finally to destroy the morphologic entity of the bacilli in order to obtain unobjectionable results. In other words the essential toxins (some writers it is true, assert that there are no essential tubercle toxins) are not excreted like they are in cultures of diphtheria bacilli, but they are to the far greatest extent enclosed within the membrane of the bacterial cell. The culture fluids contain none, or very little of these specific toxic substances; they may be injected in comparatively large doses into animals without causing serious damage.[3] We may add right here that it seems that there are produced a number of different toxic substances, at least this would best explain the contradictory results of some observers; but we must not forget that ferments or enzymes, like the bacterial toxins, are very unstable compounds and are easily changed in their chemic nature by all kinds of artificial procedures. It is, therefore, more than likely that the different bodies isolated from tubercle bacilli or their culture media, are not pre-existing, but represent ingredients of the former in a changed form.

Surely this holds good for the old tuberculin, which has mostly been used as an immunizing agent. How little this fluid represents the active principles of the live tubercle bacillus is well illustrated by the following observation. If some of the dead and extracted bacilli which remain as residue after the preparation of tuberculin are injected into suitable animals, they not only cause the formation of typical tubercles, but even prompt these animals to yield a typical tuberculin reaction. It is well known, furthermore, that this tuberculin reaction, the nature of which has by no means as yet been explained, may be obtained by several other similar bacterial compounds (proteins) and even by heterogeneous albuminous bodies (deutero-albumoses). No matter in which way the tuberculin was prepared it is *a priori* impossible that the serum of animals immunized against it possesses any antitoxic properties as far as the tuberculosis *toxins* are concerned. A certain antituberculinic power may be exhibited by it (this is apparent especially by experiments made by Schweinitz[4], Babes[5] and others), and by it some influence on tuberculous processes may be now and then explained. In general, the results obtained with such a serum have been discouraging. The same obtains for those modifications of antitubercular sera, for the preparation of which in addition to tuberculin cultures of the bacilli, dead or alive, have been utilized. As said above these bacilli are very slowly resorbed, the greater part of them is ejected in the pus of abcesses formed at the site of the injection. It must not be denied, however, that in some instances the results thus reached were fairly promising. This refers especially to the work of Niemann[6] and Babes[7], who really repeatedly immunized guinea pigs in this way against inoculation with living bacilli. This proves that the serum prepared by them possessed distinct antitoxic (according to Babes even bactericidal) properties. But they also operated only with a part of the active principles of the tubercle bacillus, and accordingly the outcome of their labors lacks consistency and certainty. In no case out of the great number of respective investigations was a stage reached in which the observer could with certainty foretell the result of an experiment.

That both antitoxic as well as bactericidal potencies must be qualities of an antitubercular serum, is shown by the well-known phenomenon that we sometimes have to deal with an infectious, mostly with a toxic type of the disease; that living bacilli, furthermore, as such are less apt for the production of such a serum than dead ones (that means bacilli easier accessible to disintegrating influences) is indicated by the enormously larger toxicity of dead bacilli[8]. It may be well in this connection to mention the important fact that from the tuberculous organs of infected animals an extract can be prepared, that while being exceedingly toxic when injected in gradually increasing doses into guinea pigs, in a short time immunizes them against the introduction of virulent cultures[9].

If so it goes without saying that "antituberculin sera" are not what must be claimed from an antitubercular serum; there are certain direct drawbacks attached to them, that under circumstances have proved very obnoxious. In the first place the assimilation of the tuberculin by the animal organism is a slow process; it may happen that the serum of these animals contains unchanged tuberculin instead of antituberculin. The following experiment illustrates this fact: A healthy guinea pig received in seven doses during twenty days as much as 10 c.c. of tuberculin. Ten days after the last injection some blood was drawn from this animal; 1 c.c. of the serum of this blood was sufficient to produce a typical and very violent tuberculin reaction in a tuberculous guinea pig. This phenomenon is at the bottom of what in the literature is known as transmitted tuberculin-action. Its undesirability is evident.

TABLE 1.—Influence of T.R. serum on the temperature of healthy guinea pigs.

Date.	Number of guinea pig.	Weight in grams	Amount of serum injected.	Temper. before injection.	Three hours later	Six hours later.	Nine hours later.	Twelve hours later.

Again, it is little known that bacterial proteins in glycerinic extracts, when administered for any length of time, invariably tend to produce a chronic nephritis. Niemann[10] first called attention to this fact, and I found it confirmed in two horses which for some months had been treated with high doses of tuberculin. It is not impossible that the fatal effects, which these sera sometimes have on animals, are due to uremic products retained in the blood serum. Babes[11] saw guinea pigs die from the injection of 0.5 c.c. of such a serum; Rutkowski[12] relates similar accidents in his report on Vicquerat's antitubercular serum. I myself saw repeatedly guinea pigs die in a very short time from the injection of 0.5 to 1 c.c. of Paquin's serum. The autopsy (death in diastole) did not reveal any definite cause of death.

The foregoing somewhat lengthy remarks were necessary in order to show that the solution of the tuberculosis serum problem depended upon the discovery of some means of making the tubercle bacilli with all their constituents easily resorbable. I did not fail at once to see that with Koch's new tuberculin, T. R.,[13] this means was given, and immediately set to work to follow out this idea. But I would not like to be understood as if this work claimed to be something original; logically the thought was bound to offer itself, and in addition to this, Koch himself had insinuated it. While my experiments were going on, I had the satisfaction to hear that Behring[14] was following the same lines, though no details whatsoever about his investigations have as yet reached this country.

It need not concern us here that at the present time a hot war is raging as to the therapeutic value of this new tuberculin; in contradistinction to other observers,[15] I can confirm Koch's statement about its immunizing properties toward animals. But the salient point was that at last in it we had a substance which exhibited, in full and unchanged, all of the toxic ingredients of a tubercle bacillus. We have seen before that the culture media of tuberculosis cultures contain only a very small amount of toxic bodies, most likely the outcome of disintegration of the bacilli.[16]

If, therefore, a conclusion *per analogiam* was allowed, this new tuberculin (T. R., I shall henceforth call it), by immunizing animals was likely to produce the desired antitoxic effects, if such effects could be obtained altogether. Within the limits of our present knowledge no other means of doing this could be conceived.[17] I began experiments in this direction, and the following remarks will give their results:

According to Koch's directions, a greater part of the tuberculous toxins is excluded under the name T. O.; this T. O. contains those toxins that are contained in the adhering traces of culture media, as well as those that easily are extracted from the membranes of the bacilli. They do not seem to have a great immunizing power, but are exceedingly toxic and resemble in their effects, in many regards, the old tuberculin. But try as I might, I could not convince myself as to the logical necessity to exclude this part of the toxins from the immunizing process, so much the less since in my animals I did not need to be afraid of any, and even very severe, reactions. The same, I thought, applied to the fraction of toxic substances contained in the culture media. To express myself candidly, I did not want to take any chances in omitting some toxic body that afterward perhaps might prove of intrinsic value, although I knew that T. R. alone would immunize my animals against these substances. I used only strong and perfectly healthy horses.[18]

The way in which I proceeded may be described as follows: I began with the injection of 1 c.c. of T. R., which did not cause any reaction whatsoever; in the subsequent injections, which were made about every seven and ten days, the amount was about doubled each time until 30 c.c. of pure T. R. were reached. The reactions so far were very slight, the temperature never rising more than 1.5 degrees F. At this stage I commenced adding small amounts of T. O., as well as an aqueous extract of the nutrient agar; the reactions were very severe, sometimes reaching perfect prostration. Mostly a profuse diarrhea set in; after a temporary fall the temperature rose to 104 and 105 degrees F. Loss of appetite occurred, etc. In four or five days these symptoms disappeared. Sometimes abscesses formed, caused by some undestroyed tubercle bacilli. Gradually and cautiously I reached a combined dose of 75 c.c. of T. R. and 30 c.c. of T. O. The indications are, however, that much higher amounts will be tolerated, and I do not propose to stop before external reasons call for a halt. Both preparations, T. R. and T. O., were prepared in my laboratory, and the culture I used was of such a virulence that the *dosis minima*, when injected into the abdominal cavity of a guinea pig (about 500 grams), killed the animal within ten to fifteen days. As *dosis minima* I came to consider one loopful of an emulsion obtained by thoroughly triturating one loopful (1 mg.) of a four weeks agar culture with 1 c.c. of sterilized water. Smaller doses produced a protracted course of the disease; the latter then invariably attacked the lungs. The toxic power of this culture was so great that about 16 mg. of the dried and finely triturated bacilli killed, within twenty-four hours, guinea pigs of the above average weight. Therefore, if with Behring we call *m* the fatal dose of toxin for one gram of guinea pig, my culture possessed a toxicity of 30,000 t. m. I tested its toxicity during several generations, but did not find any material deviations. Cultures of a different origin showed only a potency of 400 and 2,000 respectively. A culture of aviary tuberculosis goes as low as 260. We must not lose sight of the fact that these figures only hold good for guinea pigs.

The first blood was drawn after a T. R. dose of 50 c.c. (+ 25 c.c. T. O.) was reached, and with the serum obtained from this blood the following experiments were made. I will remark, however, that the serum from later bleedings (after larger doses of the immunizing fluid had been administered) showed in all essentials the same characteristics, only in an intensified degree. For my experiments I used guinea pigs, monkeys, and to a certain extent rabbits. I preserved my serum by the addition of camphor, 0.5 per cent. phenol or 0.3 per cent. trikresol. The action of the serum on a healthy animal is only noticeable by a slight fall of temperature two or three hours after the injection (Table 1); this fall of temperature ranges from 0.5 to 1 degree. Comparative experiments (Table 2) with normal horse serum demonstrated, however, that here too the same phenomenon could be observed. The amount injected varied from 0.25 c.c. to 2 c.c. Otherwise, no local or general reaction occurred.

In order to determine the presence of any immunizing power of our serum, in one series of experiments (Table 3) five guinea pigs were treated during thirty days with repeated injections of .25 c.c. of the serum; they received altogether 4 c.c. of serum each. After thirty days three of them were inoculated with the fatal dose of tubercle bacilli, the two remaining ones being kept as controls. At the same time two fresh animals received the same fatal dose of bacilli. The result was that after twenty-four, respectively twenty-one days, the two non-treated animals died with the typical lesions of tuberculosis, while the three inoculated ones, as well as the two controls, remained healthy and continued to gain in weight, the same as they had done during the serum treatment. After six weeks one of the infected animals was killed; the autopsy did not reveal any lesions whatsoever, neither at the point of injection, nor elsewhere.

Two other sets of five animals each were subjected to similar conditions, only the amount of serum and number of injections varying. One series (Table 4) received during thirty days five injections of .25 c.c. of serum each. Of three animals of this series inoculated with the fatal dose of tubercle bacilli, one died after twenty days: the two others showed extensive infiltration around the point of injection, but no ulcerations. They did not lose in weight. Whilst this experiment shows that the quantity of serum was insufficient for complete immunization, its effect is nevertheless very apparent.

The third series was treated during the same length of time with five injections of .50 c.c. each. Then three of them were inoculated. All animals remained well and continued to gain in weight (Table 5).

Though these experiments comprised only seventeen animals, the evidence brought out by them may well be considered conclusive in view of the fact that even an intraperitoneal inoculation (Table 3, No. 21), which otherwise invariably results fatally in a short time, did not cause any lesions whatsoever.

Naturally, as the next step in my investigations, the question offered itself, how the serum would influence tuberculous infection, when applied at the very moment of infection. Various amounts of serum were therefore mixed with the fatal dose of bacillary emulsion, the mixture being injected subcutaneously or into the abdominal cavity. Of three guinea pigs which in this way received 1 c.c. each, not a single one showed any signs of infection; the same obtained for six others into which 0.5 c.c. each was injected and for the third set of three to which was given .25 c.c. each. When I lowered the dose to .10 c.c. the results became valueless (Table 6). As controls for this experiment two sets of three animals each served, one being inoculated simply and left without treatment, while the second set received with the bacilli .25 c.c. of Paquin's antitubercle serum. All six animals died within the usual time, two of the last (Paquin) set before the others.

We will see later on that our serum possesses very decided bactericidal properties. For this reason the experiments of the last series had to be varied so that bacilli and serum were injected at the same time, but each for itself, and in a different place. In this way three guinea pigs were treated, receiving the virus on the back, and the serum (.50 c.c.) on the abdominal aspect, as nearly as possible at the same time. They remained in perfect health, except No. 12, which showed, eight days after inoculation, a slight enlargement of the inguinal glands. The latter disappeared, however, in a short time, and the animal is as healthy today as are its mates (Table 7). After these tests the most difficult problem remained to be solved; how far advanced may a case of guinea pig tuberculosis be, in order to be amenable to a curative treatment by this serum? The number of my experiments bearing on this question is, I confess, but limited; I could convince myself that with almost absolute certainty one succeeds in saving the life of the animal when treatment is begun within the first ten days after inoculation with my culture. This time limit reached, the results became uncontrollable. I instituted treatment in several series four, seven and ten days after inoculation; injections (uniformly .25 c.c.) were given regularly every other day for four weeks; after that time one injection per week was deemed sufficient. Of eighteen animals I have lost, until the present date, not a single one, though in one an enormous glandular enlargement has developed. The characteristic ulcerations at the sites of inoculation are absent, and the temperature is normal.

Although I would not like to appear over-confident, the time elapsed since treatment was begun being only two and one-half months, I may safely assert that I consider those animals as recovered. In three of them I made the routine tuberculin test after six weeks of treatment without obtaining a reaction (Tables 8 to 11). Wherever ulcers had formed before the treatment they healed readily, no symptoms remaining to indicate a pathologic condition. The temperature was easily reduced to normal (Table 12); the weight kept steady or increased slightly.

Two animals of series 10 were sacrificed after seven weeks, to enable me to study the pathologic anatomy of the diseased organs. The liver showed those peculiar cicatricial ridges described by Koch as characteristic after T. R treatment. The spleen in one case was extraordinarily contracted, etc. In one word, everywhere successful attempts at restitution or at least at encapsulation were obvious, the latter especially in diseased lymph glands. A description *in extenso* of these very interesting changes I must reserve for some future time, after my animals have been observed for a longer period. As controls, I used again some animals simply inoculated with bacilli, and some others which in addition received the benefit of the Paquin treatment. All of these animals died in due time.

For brevity's sake I omit to mention a number of other experiments destined to investigate the protective and curative potency of the T. R. serum. Those that have been reported are more than sufficient to establish the fact that this serum not only protects guinea pigs against infection, but that it is too, of a very powerful curative potency.

Very gratifying was also the outcome of some experiments made on monkeys (belonging to the genus *Cebus*, of the order of the *Platyrrhini*). On July 22, two of them were inoculated with .25 c.c. of bacillary emulsion into the abdominal cavity. While one served as control, the other was treated to regular injections every other day, of .50 c.c. of T. R. serum; this treatment was begun the day after inoculation. Very soon, in the control animal, high temperature set in (rising to 105 and 106 degrees), emaciation became visible, and on September 10 death occurred from the most extensive visceral tuberculosis I ever saw. The lungs were not affected at all. His more fortunate mate is today alive and healthy, and did at no time exhibit any symptoms of infection. His temperature remained perfectly normal, his weight increased slightly and some days ago he did not react at all after .15 c.c. of the old tuberculin was injected subcutaneously.

Very satisfactorily, too, resulted an experiment on two other monkeys, into the trachea of which, after tracheotomy had been performed, .25 c.c. of bacillary emulsion was injected. Treatment of one of them was begun immediately after inoculation (August 16) in the way described in the former experiments. The control animal died September 5 with very extensive lesions of the larynx, lungs, liver and the whole lymphatic system; an enormous tuberculous ulcer had developed at the place where tracheotomy was performed. Emaciation was very marked, as well as the anemia. In contradistinction, the other animal kept a steady temperature and weight, and offered no sign of disease, except a small ulceration of tuberculous nature at the place of incision; I feel sure that prolonged treatment will cure him entirely.

For certain reasons I would like to omit here a report of experiments with intraocular inoculation of rabbits. The well-known uncertainty of such experiments arising from very marked differences in the susceptibility of these animals is an element that prevents conclusive deductions. May it, however, be said that when inoculation and serum injection were practiced at the same time, in no case an infection was effected. The results varied whenever four or more days intervened between the two.

However tempting and alluring the reported results may appear to one uninitiated into the deceptive phenomena and phases of experimental tuberculosis, I will make haste in accentuating the fact, that *per se* they do not form conclusive evidence as long as the animals have not been observed for a longer period (five to eight months). In order not to be misunderstood, I must repeat that the period of my observations extends only over two and one-half months. But combined with the following considerations they form an absolutely safe stronghold. If the T. R. serum acted specifically, this must be due to antitoxic or bactericidal properties; it became necessary, therefore, to demonstrate the latter.

The slowness of growth as well as their peculiar cultural arrangement compelled me to submit the tubercle bacilli to the following procedures, which entirely differ from the usual method of determining the bactericidal power of a fluid. A number of sterile test-tubes were filled each with 5 c.c. of fresh T. R. serum. A few drops of an emulsion of tubercle bacilli were added to each of these tubes, whereupon the whole series was put into the incubator. After the lapse of a certain time the single tubes were removed and 1 c.c. of their contents injected intraperitoneally into healthy guinea pigs. Table 13 gives the results *in nuce*. It was found that a contact of the tubercle bacilli with the serum during five hours, was sufficient to destroy their vitality, or at least to impair their power of resistance so much, that the animal organism could easily rid itself of them.

The only attempt at determining this bactericidal power of an antitubercle serum, that I could find in the literature, was made by Babes,[19] but the bacilli in his case were killed only after a contact of twelve days duration. I do not know but what the addition of a preservative will decrease this power in my case to a certain degree.

In the search for antitoxic properties, the customary methods of combining the serum with a certain amount of old tuberculin (either fatal or just sufficient to bring about the characteristic tuberlin reaction) offered itself first. Babes and Schweinitz in this way proved the "antitoxic" nature of their sera. So did Niemann. But according to what has been said above, the only thing proven by these tests is their antituberculinic nature, which will be present, too, in a really antitoxic serum, but at the best only forms a part of its potency. That, by the way, not even this antituberculinic quality is possessed by some of the "antitubercle" sera, has been shown by Behring (l. c.), who found that Maragliano's serum is perfectly void of it. As to Paquin's antitubercle serum, I repeatedly came to the very same negative result.

How my T. R. serum behaves in this regard will be seen from table 14. I found that .50 c.c. of it is sufficient to save a tuberculous guinea pig from the fatal dose (.20 c.c.) of tuberculin, and that .1 c.c. prevents the tuberculin reaction (.10 tuberculin). The tuberculin that I used was of a strength that 1.5 c.c. killed a 500 gram healthy guinea pig within twenty-four to forty-eight hours; I prepared it from cultures of my virulent bacilli. Niemann for his serum, found the relation 7 to 1, while in our case it would be 1 to 1.

But since it was evident that tuberculin did not mean tuberculosis toxin, I worked out another method, which with due regard to the incompleteness of our knowledge gave very satisfactory results.

I profited by Koch's investigations, combining T. O. with T. R. and so getting a fluid which contained, in an absolutely unchanged form, all of the substances (toxins, etc.), the effect of which on the animal organism was to be studied. After the whole of the bacilli had been thoroughly triturated, I gauged the suspensions of them so that every c.c. of the 20 per cent. glycerin solution contained 1 mg. of solid substance. Doses up to 8 and 10 c.c. of this fluid were borne by healthy guinea pigs without any trouble; higher doses produced irregular fever and infiltration; 15 to 16 c.c. invariably caused death.

Quite different was the action on tubercul[illegible] animals; 1 mg. always produ[illegible] in thirty-[illegible]rs. an extended inflammat[illegible] ion, and [illegible]y fever reaction differing [illegible] tubercul inasmuch as the rise of temperature appears rather sudden (two or three hours after injection) and keeps steady for ten to twelve hours, after which time a decline by lysis occurs. The infiltrations disappear within three days, usually. Very characteristic and interesting is the fact, that in one and the same animal such a reaction may be elicited indefinitely, by only a slight increase of the dosage (Table 15). The common tuberculin reaction, in the same animal, usually fails the third or fourth time. I do not know yet what influence our reaction has upon the tuberculous lesions; existing ulcers heal readily.

If instead of 1 mg. we use 2 mg., this dose invariably produces death within twenty-four hours.

Before we can utilize this toxin for determinations of the antitoxic value of our serum, one objectionable feature of the test will have to be removed, the inequality of the extent of the tuberculous lesions in the animals used. Although in guinea pigs the disease partakes of the character of a self-limited trouble, the extent of the lesions and the constitutional conditions vary enormously in different animals inoculated at the same time. The reactive capacity, naturally, varies with these conditions so that, although for qualitative tests any animal, provided it be tuberculous, will be satisfactory; this is not so for quantitative determinations. Here we must be, as far as possible, sure to always encounter the same power of, or rather lack of power of, resistance in our animals.

The beautiful investigations of Borrel[20] and Kaspareck[21] furnished the material to obviate this difficulty; while the former demonstrated the fact that as soon as thirty-six to forty-eight hours after inoculation, tissue changes became observable, the latter added the valuable information that for the appearance of the tuberculin reaction such tissue changes are necessary, and that this reaction may be typically observed about thirty-eight hours after infection. The eminent theoretic importance of these two facts is apparent (perhaps especially with regard to an alleged pre-tuberculous stage of the disease). I found in them a means to procure for my tests a nearly always equivalent material. If into healthy adult guinea pigs of about the same weight (500 to 700 grams), always the same amount of virus (one loopful of my culture) is injected, and if at a stated interval afterward (forty-eight hours) the same amount of T. O. and T. R. toxin, together with the serum to be tested, is administered, we have done as much as can be done in order to obtain comparable results.

Preliminary experiments showed me that 1 c.c. of my toxin injected into these forty-eight hour guinea pigs elicited the above described reaction, together with a very marked infiltration, while 2 c.c. were here, too, found to be the fatal doses.

By such experiments I knew also that less than 1 c.c. of my serum inhibited all these reactions. If, therefore, we agree to call an antitoxic unit 1 c.c. of that serum which counteracts 1 mg. (1 c.c.) of toxin (always supposed that the serum has been prepared by means of the same race of bacilli from which the toxin is derived), it was easy to determine the potency of the serum under discussion. Accordingly a number of guinea pigs, of about 500 grams weight, were prepared in the way described, whereupon various amounts of serum, each mixed with 1 c.c. of the toxin were injected after forty-eight hours. While .3 c.c. were not able to materially influence the reaction, with .4 c.c. no temperature reaction, nor local infiltration occurred; .6, .8, and 1 c.c. acted in the same way. This means that the serum is 2.5 times more active than a normal antitoxic serum. In other words, that it represented 2.5 antitoxic units to the c.c. This seems to be a very low value, when compared with the potency of other antitoxic sera. But the serum of the same horse one month later, after immunization had been continued all the time, showed a potency of 3.7. The serum of another horse was found of a strength of 2.8 the first time, of 4.1 six weeks later. These findings I believe to be the most valuable part of my work, since they justify the hope that in due time a serum of very high power may be obtained.

On the other side we must not forget that our serum is not only antitoxic, but in a very high degree also bactericidal, the latter quality being, under certain circumstances, probably more valuable than the former. Furthermore, I think it highly probable that later on a tubercle virus may be obtained of much greater toxicity. Some experiments are under way to find out whether after a method similar to that of Metchnikoff, Roux, and Salimbeni[22] (cultivation of tubercle bacilli enclosed in small pouches of collodion which are introduced intraperitoneally into guinea pigs or rabbits), still more virulent forms may be obtained. Be that as it may, my researches so far have demonstrated *the fact that a serum both antitoxic and bactericidal may be obtained by immunizing horses against tuberculosis by the new tuberculin T.R., and that it is possible to immunize (and cure) guinea pigs with perfect certainty by means of the serum for which I propose the name "Antiphthisic Serum, T.R."*

It would be unnatural not to consider the possibilities that my serum may hold out for the treatment of human tuberculosis, although it is with great reluctance that I venture to make a few remarks on this point. After what has been said in the beginning of this paper, I take the applicability of antitoxin treatment in human tuberculosis for granted. Moreover, the chronic form in which the process usually is met with in man, has certainly to be considered as a favorable point. It can be shown experimentally that the relative toxicity of the watery extracts of finely ground tissues of the organs of tuberculous guinea pigs is enormously higher than that of human tuberculous tissues, in other words, this very chronicity is indicative of a process less productive of toxins. As an admissible objection it might be said that one is not allowed to infer from phenomena observed in one animal, or those observed in another. The more penetrating our investigations become, the more we are forced to admit that the virulence and toxicity of a micro-organism, is by no means the same upon different animals. I think, however, that in the case of the tubercle bacillus, though for obvious reasons a direct proof can not be had, we are perfectly safe in surmising that these differences, if existing at all, are only differences of degree and very slight ones too. In the multifariously confirmed tranmissions from animal to man. and *vice versa*, I am inclined to see a confirmation of this surmise.

The antitoxic potency of my serum seems as yet, when compared with other antitoxic sera, to be small, but I do not know whether we have a right to doubt *a priori* its efficacy in man on that account; in the first place, we do not as yet know anything with certainty about the way in which this antitoxic property exerts itself, and whether we are allowed to estimate it quantitatively.[23]

But besides this it is a fact that the main toxic action is not exerted by the living bacilli, but by the dead and disintegrating ones, so that a smaller amount of antitoxic power supplied continually will be likely to meet all exigencies. These, however, are problems to be solved in the future. I will only repeat that there seem to be theoretically no limits to the degree of the antitoxic potency, and that practically it is a matter of time and, since T.R. is a rather expensive article, of financial considerations.

The value of T.R. serum for human patients can only be ascertained by a prolonged observation. In about twenty cases so far treated by me and several physicians in and outside of St. Louis, the results have been exceedingly gratifying. I need not tax your patience by telling you what kind of cases we may reasonably expect to be benefited by such treatment. I must lead your attention, however, to the statements of Spengler,[24] asserting that a great number of so-called mixed infections are not *a priori* to be considered as hopeless, but that secondary infection very often rapidly subsides and disappears, as soon as some curative influence comes to bear on the tuberculous process.

All of the cases treated, so far as the reports show, were early cases of pulmonary affection; a positive diagnosis was made in every one of them by microscopic examination. In all of these cases, within six to eight weeks a very decided improvement was brought about; temperature became perfectly normal; cough, expectoration, and night sweats stopped; uniformly a considerable increase in weight was observed. The pulse became normal, number of respirations decreased, etc. In all cases, physical examination showed an arrest of the active process, and a clearing up of the affected area; in those cases observed by me the moist râles disappeared within four weeks after treatment began. The latter consisted in daily hypodermic injections of 1 c c of the serum. No local or general reaction resulted except now and then a little soreness and swelling around the site of the injection. The most noticeable fact was the lowering of the afternoon temperature, which sometimes would be observed after the first few injections

I would, however, not like to lay myself open to the reproach of hasty conclusions in a subject the chief element of which is time. A more extensive report will be rendered after the necessary time has elapsed

The scientific gain of my investigation is the preparation of a really antitoxic and bactericidal antiphthisic serum. With a probability next to a certainty we may expect this serum to become an important factor in the preventive and curative treatment of human tuberculosis; the "importance" of the declining attitude of the Moscow Congress toward serum treatment in tuberculosis will, I am sure, dwindle down to the insignificance and worthlessness inherent to all judgments and criticisms of gregarious masses.

METRITIS.

BY BYRON ROBINSON, B.S, M.D.

Professor in the Chicago Post-graduate School of Gynecology and Abdominal Surgery, Professor of Gynecology in the Harvey Medical College and the Illinois Medical College, Gynecologist to the Woman's Hospital, Gynecologist to the Woman's Charity Hospital, and Consulting Surgeon to the Mary Thompson Hospital for Women and Children
CHICAGO

For many years I have been observing in the practice of gynecology a peculiar disease of the uterus characterized by hypertrophy, atrophy or induration. In the chronic state the uterus is hard in consistence. Its walls are rigid and stiff. The disease may occur in a girl of 15 years, or in woman before or after the menopause. It is known as metritis, *i. e.*, an inflammation of the uterine muscularis I shall attempt to bring forward some views on the disease by the aid of carefully drawn microscopic illustrations. In the

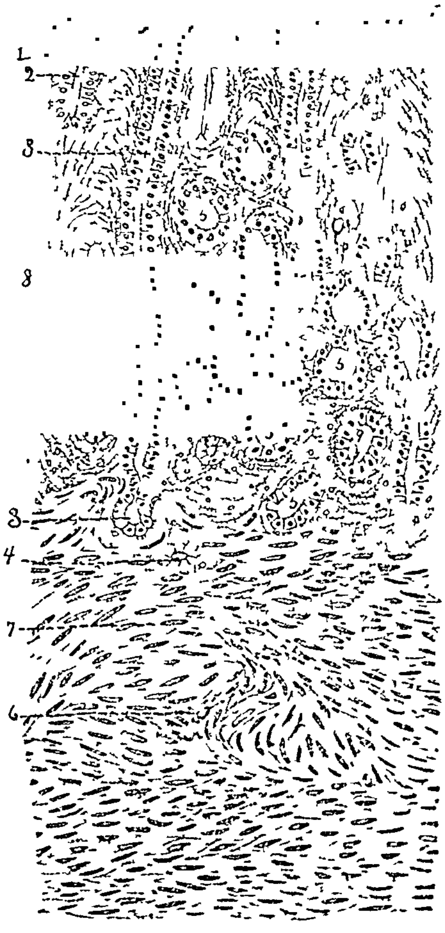

Figure 1 represents a uterus, mucosa and muscularis, in the quiescent stage, in the state of rest, i e, midway between two menstrual periods. 1, 1, the columnar nucleated, ci[illegible] sing[illegible] [illegible] uterine epithelium; 2 a part of a utricular [illegible] [illegible] surface of the mucosa; 3, a whole utricular [illegible], extend ing from below the level of the muscularis to the internal surface of the mucosa. It is lined by a single layer of distinctly nucleated cylindric columnar (and ciliated ?) epithelium. Observe how it ends in the muscularis and how the muscular trauma or contractions could induce the migration of contained pathogenic microbes into the field of the muscularis, producing inflammation and its results; 1, represents the tip end of a utricular gland far beneath the surface of the muscularis; 5, 5, 5, 5, 5, 5, show empty, resting utricular glands cut at varying angles to the longitudinal axis, 8, points to the lymphoid tissue composing the mucosa, i e., the connective tissue cells and fibers, the blood and lymph vessels; 9, 9, shows resting glands containing a little mucus; 6, shows a blood vessel in the muscularis, and 7 points to the nucleus of the unstriped muscular cells. The two characteristic structures observed are: *a*, the mucosa containing utricular glands, connective tissue cells and fibers, blood and lymph vessels; *b*, the muscularis containing unstriped muscular fibers and blood vessels; and *c*, the peculiar anatomic *fact that the glands of the mucosa dip down into the muscularis*. There is no submucosa in the uterus. The muscularis is not protected from the mucosa by a submucosa, and hence the easily infected utricular glands quickly carry infection into the unprotected muscularis. Other hollow viscera like most of the digestive tract are protected from infectious invasion by a layer of tissue, the submucosa, which separates the glandular, the mucosa, from the muscularis. Besides, the submucosa, e g., in the stomach, allows a wide, independent movement of the mucosa and muscularis. In the uterus the mucosa and muscularis are immovably fixed on each other. Observe the solid, compact glands and tissue in the uterine mucosa and the small nucleus of the muscularis in the resting uterus.

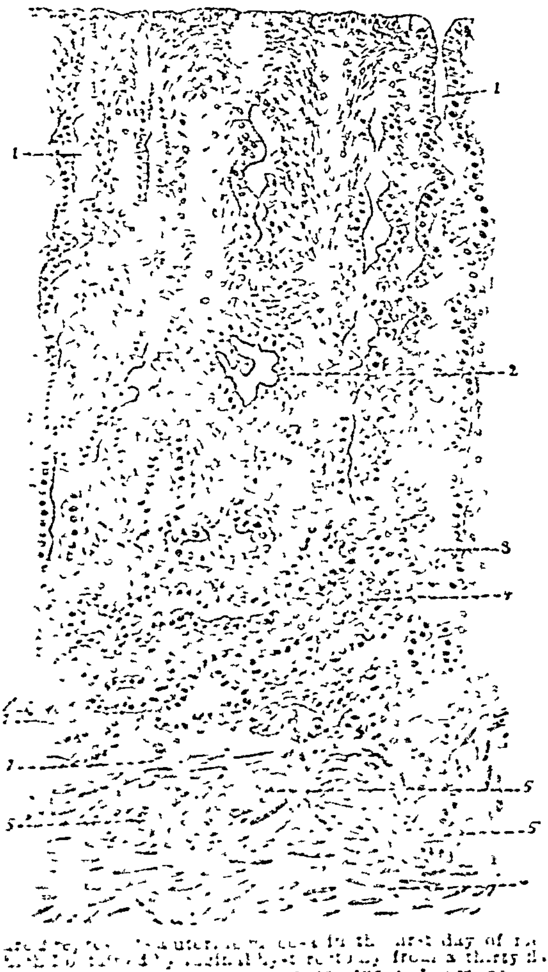
illustrations I have attempted to show typical specimens of a quiescent uterus or one at rest, one specimen of a uterus in the first day of menstruation, and a specimen of about ten weeks' pregnancy, and two more sections cut at right angles to the utricular glands. The specimens should be studied comparatively to observe the vast yet gradual difference occurring in the uterine mucosa.

Metritis is one of the most frequent diseases of women. About ten women out of fifteen who come to the clinics have a distinctly palpable metritis, over the diagnosis of which no dispute may arise. Metritis occurs in all grades, from the sensitive, acute to the stage where little sensation remains.



[illegible] uterus [illegible] in the first day of menstrua- [illegible] from a thirty [illegible] year [illegible] the mucosa and the [illegible] is almost doubled in [illegible] with folded [illegible] several utricular glands [illegible] muscularis than in the resting

uterus. Note the increased size of the nucleated, columnar epithelium in the menstrual uterus over the resting uterus. The interglandular substance, the lymphoid elements, connective tissue cells and fibers, the blood and lymph vessels, are all vastly increased over the resting uterus. In the menstruating uterus the muscularis, the nuclei of the muscular cells, are about doubled in length and breadth. With good specimens one can observe the large amount of fluid lying in the tissue and forcing the elements wide asunder. Also the ubiquitous leucocyte aids to increase the thickness of the muscularis, and especially the mucosa, in the menstruating uterus Especial attention is directed here to the fact that the columnar, nucleated endothelium lining the mucosa and utricular glands, is nowhere (first day of menstruation) shed, but intact everywhere, and *nearly double the size of that in the resting* uterus. 1, 1, represent almost complete utricular glands cut longitudinally, 3, points to the bloody debris found in this sinuously dilated menstruating gland which opens on the internal surface of the uterine mucosa *and dips deep down into the muscularis*, 2, points to a widely open utricular gland with enormously developed epithelia; 1, points to the vastly increased interglandular substance, lymphoid elements, connective elements, blood and lymph vessels, all forced asunder by edema, infiltrated fluid; 5, 5, 5, 5, point to utricular glands buried beneath the muscularis, and 5¹ can be traced from the internal surface of the uterine mucosa to a long distance below the surface of the muscularis. The bloody debris in the utricular gland found deep in the uterine muscularis demonstrates that it is actively engaged in the act of menstruation; 6, points to the vastly increased size of the nucleus of the muscle during menstruation. The mucosa and muscularis alike engage in the great change accompanying menstruation, i.e., violent glandular and vascular changes.

As an explanation of the tendency of the uterus to inflammation over other organs we must look to its peculiar structure. It may be stated without fear of successful contradiction that the uterus is not only prone to inflammation, but it is prone to harbor it for an indefinite period. The carefully prepared cuts accompanying this article, drawn from my own specimens, will explain the mechanism a thousand times better than words. The uterine wall consists of three tunics, viz.: tunica mucosa, tunica muscularis and tunica serosa.

First, the uterine mucosa, the endometrium, the tunica mucosa or propria, or the lining membrane of the uterus furnishes the clue. It is composed of tubular glands standing nearly at right angles to the uterine wall. These glands (glandulæ uterinæ, utricular glands) are lined by a distinctly nucleated columnar ciliated epithelium. The ground work sustaining the glands consists of a peculiar connective tissue cell and a connective tissue fiber. The mucosa is rich in this lymphoid embryonic-like tissue. It is also rich in blood vessels and abundant lymph elements. The uterine mucosa undergoes variable changes during the subject's seedtime and harvest. At the menstrual time it is often doubled in thickness, becoming about one-fifth of an inch thick. During gestation, the mucosa undergoes considerable changes, but apparently not so violent and rapid as at the monthly period. The three chief changes of the mucosa at menstruation and gestation are: 1, Elongation and sinuous dilatation of the glands; 2, Enormous distension of the blood and lymph vessels; 3, Increase of interglandular substance by multiplication of the embryonic type of connective tissue cells and fibers, the migration of red and white blood corpuscles and the infiltration of the mucosa with fluid.

The significant vascularity (blood and lymph vessels) and the predominent glandularity (lymph elements) characterize the uterine mucosa and mark it as a field rich in susceptibility to infectious invasions, and since the uterine mucosa is not only directly exposed to the external world, and especially to sexual imprudence and consequent infection, but also to the violent congestions of menstruation and the rapid changes of gestation, it is no wonder that its delicate structure and wonderful function becomes impaired.

Now, the significant peculiarity of the uterine mucosa is, that it rests directly on, and some of its glands penetrate, the uterine muscular wall. There is no submucosa in the uterus. There is no barrier to infectious invasion from the uterine mucosa to the uterine muscularis. *Infection can travel directly, by way of* the utricular glands, into the muscularis. No military trocha exists between the mucosa and muscularis in the uterus to prevent general infectious invasion. No finely woven connective tissue, submucosa, forming a distinct barrier, a partially impenetrable layer to infection, is found in the uterus.

The wonderful mobility of mucosa on the muscularis, which so typically exists in the gastro-intestinal tract, does not occur in the uterus. The uterine mucosa and muscularis do not move independently of each other. They are intimately bound and connected together. In this intimate and close connection of mucosa and muscularis, perhaps is also found an explanation of further infectious invasions from muscular trauma on the utricular glands. We may call a menstruation a diminutive labor. In menstruation and gestation, the uterus is in a constant rhythm or fine small waves of contraction. Now, we observed that some of the utricular glands dipped their proximal ends a considerable distance down into the uterine muscularis. In the menstrual period the muscular waves or contractions are vigorous and active; the muscular contractions are continually traumatizing, continually disturbing the ends of the utricular glands which lie among the contracting muscles, and hence will induce the migration of pathogenic microbes through the glandular wall into the connective tissue of the uterine muscularis, with consequent inflammatory process. Muscular trauma on contained glands holding pathogenic microbes aids to spread infection. The congestions of the uterus induce muscular contractions and this process, being often repeated, allows frequent opportunities for progressive infection.

Muscular trauma must be an admitted factor in the production of disease; it disseminates germs, especially from glands to adjacent tissue, it disturbs the blood vascular and lymph vascular system and the frequent muscular activity of the uterine muscularis on the uterine glands, which are not protected by a submucosa, traumatizes them and aids to disseminate their pathogenic contents.

The first consideration in metritis is to study how metritis arises. Why does a woman have metritis, with hypertrophy or atrophy, at any time from puberty to far beyond the menopause? When a girl has her first menstruation the os dilates, the mucosa swells and becomes intensely vascular and the utricular glands dilate irregularly with sinuous and folded walls; also the muscularis is in continual waves of contraction. Intense vascularity, edema, migration of leucocytes, dilated lymphatics and highly swollen glands characterize the uterus at menstruation. In this susceptible state, a rich culture medium for germs, the uterine mucosa may become infected by microbes entering the open os from the clothing, from masturbation, from cohabitation, from the dust of the road, from the rectum, and also, it may become exacerbated from repeated menstrual processes. The resistance of her mucosa may be lowered by attacks of scarlet fever, measles, smallpox; in fact, by any acute fever. However, one of the above processes is doubtless the method by which young girls' uteri acquire metritis. Erectile tissue with congestion and decongestion alone will not explain uterine disease, because the penis passes innumerably more times through congestion and decongestion than the uterus, but does not become diseased. The element of infection must be the factor that plays the rôle in the glandular structure found in the muscularis-mucosa.

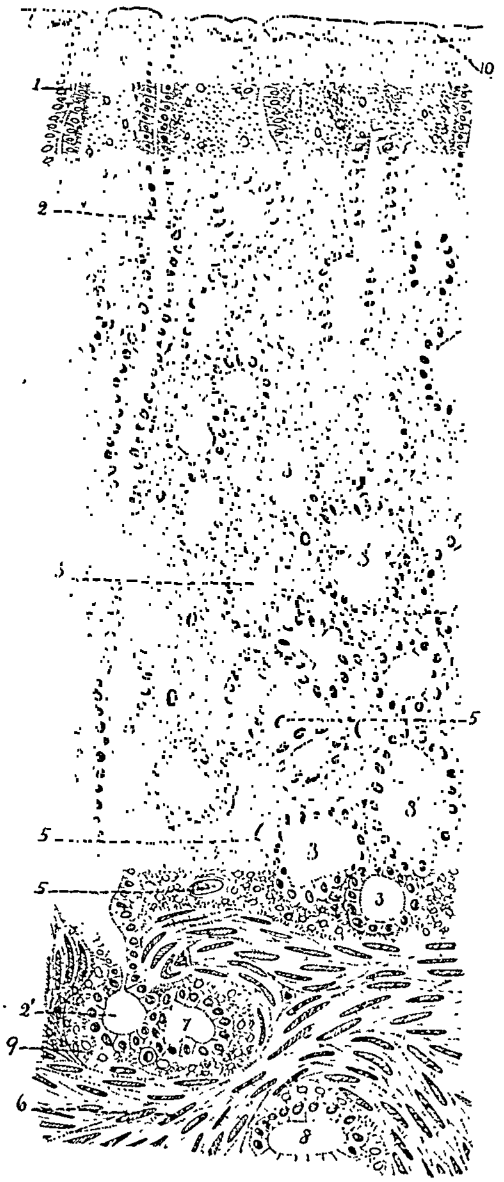


Figure 3 represents the uterine mucosa and muscularis pregnant about ten weeks *This specimen differs from the resting uterus* by hypertrophy, and from the menstruating uterus by uniform hypertrophy. In the pregnant uterus the utricular glands and blood vessels, as well as the interglandular tissue, are increased uniformly. In the menstruating uterus the utricular glands and blood vessels are not uniformly increased, but show sudden dilatation and consequent sinuous and folded walls. The glandular epithelium and the walls of the blood vessels in the menstruating uterus are much less in size than in the pregnant one. The interglandular tissue of the mucosa of the menstruating uterus is more edematous, more infiltrated with fluid than the pregnant uterus, and consequently the elements are forced wider asunder by the fluids than in the pregnant uterus. The utricular glands of the pregnant uterus do not contain blood and debris like that of the menstruating uterus. In pregnancy only mucus is found in some of the utricular glands of the uterus. The resting uterus (Figure 1) shows compact interglandular tissue and lymphoid elements. The menstruating uterus (Figure 2) shows interglandular structure, swollen, edematous lymphoid and connective elements widely separated by considerable fluids, many leucocytes, and especially sinuously dilated utricular glands with sinuous and folded walls, the glands containing bloody debris. The nucleus of the muscles are almost doubled in size. The pregnant uterus differs by a peculiar kind of hypertrophy. Its glands are uniform and smooth, and like the resting uterus, but enormously increased; they contain mucus like those of the resting uterus. The epithelia lining the internal surface of the mucosa and utricular glands are hypertrophied with enlarged nucleus. The nucleus of the muscle cells of the pregnant uterus is three to four times the size of the resting uterus and perhaps over twice as large as those of the menstruating uterus. The utricular glands of the menstruating uterus show well their penetration of the muscularis, but the utricular glands of the pregnant uterus demonstrate vastly more than deep penetration and residence of the hypertrophied muscularis. 10, represents the vastly hypertrophied epithelia of the internal surface of the mucosa; 1 and 2, point to the epithelia of the hypertrophied utricular glands; 3, 3, 3, show empty hypertrophied utricular glands, while 3' and 3' show the same with small amount of mucus; 1, indicates hypertrophied interglandular, lymphoid connective tissue and vascular elements; 5 and 5, blood vessels; 6, hypertrophied nuclei of the muscularis; 7, 8 and 2', show utricular *glands, hypertrophied, well buried, deep in the recesses of the muscularis.* Figures 1, 2 and 3 are carefully drawn from well-prepared specimens.

It may be stated that the chief forms of metritis are developed from abortion and labor. In metritis the first stage is intense congestion, venous, arterial and lymphatic. The uterus swells, considerable edema and small cell infiltration occurs in the mucosa-muscularis. The serosa does not appear to suffer so much when attacked ectoperitoneally. Chronic metritis is characterized by hypertrophic thickening of connective tissue. The muscularis may be partially or completely in a state of degeneration, fatty, pressure atrophy. Some of the muscular fibers may be entirely crushed out, while others may lie in irregular bundles. Much significance rests in the blood vessels in metritis. The vessel becomes irregular, by irregular contraction of the connective tissue bundles their lumen partially obstructed. Dilatation and constriction by connective tissue characterize the uterine vessels in metritis. The vessels may become varicose. The painful menstruation in metritis rests on the fact that the uterine vessels are surrounded by dense white connective tissue, and when the congestion and consequent expansion of these vessels occur at the menstrual period, intense pain arises from pressure on the peripheral nerves in the vessel walls and closely adjacent tissues. A well prepared section of chronic metritis looks pale and shiny, with hard, white connective tissue bundles lying irregularly in the field, interspersed with reddish masses of the muscular bundles. The enlargement of the metritic uterus may be due to the cicatrization of the muscular bundles or hyperplastic growths in the lymph spaces; perhaps both processes occur together.

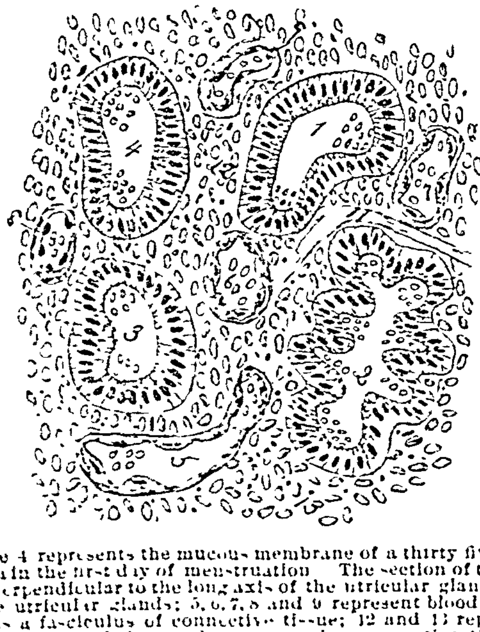

Figure 4 represents the mucous membrane of a thirty five year old multipara in the first day of menstruation. The section of the mucosa is made perpendicular to the long axis of the utricular glands. 1, 2, 3 and 4 are utricular glands; 5, 6, 7, 8 and 9 represent blood vessels; 11 represents a fasciculus of connective tissue; 12 and 13 represent the ground substance of the uterine mucosa, i. e., connective tissue fibers and connective tissue cells. In this subject the mucosa was about one-fifth of an inch thick, i. e., about twice as thick as it is in the normal resting state. First the glands are irregular, elongated and widely dilated with fluid, and the walls are especially folded and sinuous as in Figure 2. Considerable blood is plainly seen in the glandular lumen. The sudden filling of the utricular gland at menstruation does not give them time to distend uniformly; but they expand in the direction of least resistance, as is observed in every gland, but especially in No. 2. The whole mucosa and immediately adjacent muscularis is very edematous. The elements are widely distended by fluids. The lymphatic spaces are very apparent around the glands in the muscularis; [illegible] are [illegible]. The blood vessels (6, 7 and 8) are widened and filled to distension with blood. The epithelium of the glands is not [illegible]. It is perfectly intact. The muscularis is especially thickened by the distention from fluids. No. 3 doubtless represents a venous sinus cut [illegible]. This section was made near the internal surface of [illegible], hence no unstriped muscular bundles could be observed [illegible] the glands. The sinuous or folded condition of the walls of the utricular glands is [illegible] characteristic during the active stage of menstruation. In pregnancy of two to three months the glands are not larger than in menstruation, also the utricular glands [illegible] I do not show a sinuous or folded character of their walls, as is shown in the congested stage of menstruation.

The large metritic, hypertrophic uterus consists, to a great extent, of excessive growth of connective tissue in perivascular lymph spaces. Intense congestion and vascular stasis leads to overnourishment, resulting in hypertrophy. Atrophy is but a decadence of hypertrophy. The muscles are crushed out and the vascular supply gradually diminished. The contraction of the shiny, hard, glistening, irregular connective tissue bundles of the uterine muscularis leads to obstructing arterial flow and impeding venous and lymphatic (return) flow, some of the vessels assuming at first a varicose condition, and finally there exists an indurated uterus with but small and weak blood supply. The scene of the metritic uterus is almost constantly connected with endometritis. In the chronic glandular endometritis the glands may enlarge, increase in number, become occluded and dilated and project deeply into the uterine muscularis and absolutely simulate malignancy by alveolar appearances of the glands. In this manner the glandular endometrium perpetuates metritis indefinitely.

The course and prognosis of metritis is absolutely indefinite. I have treated scores of cases for at least five years. I carefully treated one case ten years for a large metritic uterus, and finally assisted Dr. Lucy Waite in performing an abdominal hysterectomy, whence the patient, from over ten years of invalidism, became well and fat in a few months. The prognosis of the metritic uterus following gonorrheal endometritis is often hopeless, because the gonorrheal infection is so persistent and continuous, inviting mixed infection, that both the mucosa and muscularis are structurally crippled beyond repair. However, many metritic uteri can be repaired so that the patient is partially well, and some perfectly well (symptomatically).

The diagnosis of metritis is easy to make (omitting the acute). With the index finger in the vagina and the other hand on the abdomen, the uterus feels hard, rigid, stiff and solid. A normal uterus should feel like a living muscle in partial tension, in slight activity. It should bend, yield and glide unimpeded in all directions. In short, it should be perfectly mobile, like a normal testicle. The metricic uterus exists in many degrees. It may feel like a muscle in vigorous high tension or as hard as cartilage or a turnip. It will not bend nor glide about normally; it is dislocated because it is permanently fixed. It is fixed by its own rigid, hard walls. The metritic uterus is always in fixed version or flexion, because (pathologic) version or flexion means fixation, it means dislocation. In this relation, four propositions may be well remembered, viz.: 1. Anteversion is where the uterus lies extended forward and is abnormally fixed. 2. Anteflexion is where the uterus is curved on its anterior surface and is abnormally fixed. 3. Retroversion is where the uterus lies extended backward and is abnormally fixed. 4. Retroflexion is where the uterus is curved on its posterior surface and is abnormally fixed.

The symptoms of metritis occupy wide fields according to its intensity and the individual susceptibility. In women the ganglionic system is developed to a greater extent than it is in men. The ganglia are not only large and more numerous, but they are richer in nerve distribution. This makes women more enduring and tenacious of life, but also it makes her more subject to reflex neurosis. The irritation arising in the uterus, an organ dominated by a rich supply from the sympathetic, like electricity streams to all other viscera. The genitals are like an electric bell button, which being pressed rings up the whole system.

Now, the learned neurologist will gravely announce that reflexes do not create deep-seated disease, and the reverse, that deep-seated disease will not be cured by removing the reflexes or its cause, to which we lend an attentive ear. However, we will claim that irritation in the (genitals) uterus, creates by reflex action disturbance in function in distant viscera. The disturbance in function soon begins a train of suffering, an impairment of health. We must say first that metritis produces symptoms of reflex irritation in various viscera, especially the stomach (digestive apparatus), and second, symptoms of pain. The manifest pain of metritis is in the pelvis, back and head. The systematic train of evils following metritis are: 1, irritation; 2, indigestion; 3, non-assimilation; 4, Anemia, and 5, neurosis. In many cases this evil train is very slow in arising.

Again, it must not be forgotten that many women have metritis with insufficient symptoms to make them conscious of its presence. I have examined many such women.

The treatment of metritis is medical and surgical.

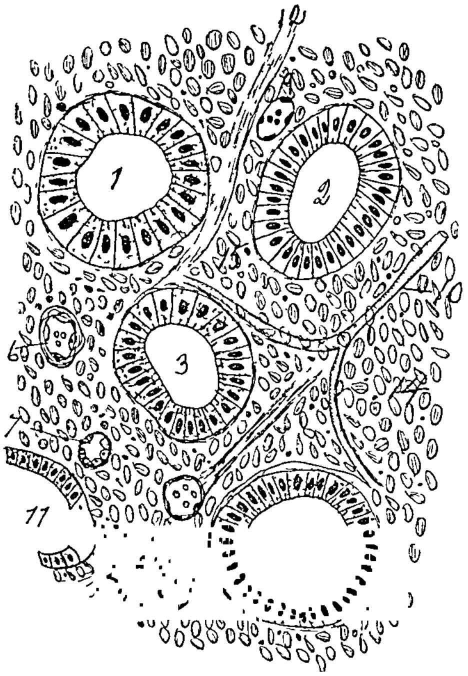

Figure 5 represents a section of the uterine mucosa of a ten weeks' pregnancy. The section is made at right angles to the long axis of the utricular glands. 1, 2, 3, 4 and 11 represent *glandulæ uterinæ*. *Observe* t uniformly hypertrophied and distended. The appear to be elongated. No. 11 represents a gland with part of its epithelia fallen out: 5, 6, 7, 9 and 10 represent blood vessels which are enlarged, but especially show thickened walls; 12 and 13 represent a fasciculus of connective tissue traversing the uterine mucosa between its glands. The ground substance, 14 and 15, show connective tissue cells and fibers, all enlarged, but it does not show the edema of menstruation. The special characteristics of pregnancy are in the uterus, uniform thickening of the vessel walls, uniform enlargement of the glands, elongation and apparently multiplication in the form of diverticular building. The muscular cells are thickened and elongated and increased in number, and the connective tissue of the mucosa is increased in its cells and fibers, in short, the glandular (lymphatic) vascular connective tissue and muscular elements seem to be not only hypertrophied, but increased in number.

First, so many women are afflicted with metritis that surgical application could not and should not be applied to but a comparatively few. The medical side of metritis is the chief one and in the majority of cases we can do much. The object is to restore the uterus to normal or to repair the damaged organ as much as possible, to relieve the patient from the accompanying reflex action and disturbing symptoms. Fortunately, for physicians, most diseases tend to get better. We can do but little for the atrophic, indurated uterus, except to relieve pain, and fortunately the atrophic indurated uterus is not afflicted with much pain. It is in the hypertrophied metritic uterus where we can do the most practical good. To treat it we attempt to limit its blood supply, in other words, to starve out the excess of tissue. This is accomplished by hot fluids, astringents and hygroscopic materials. I give the following directions for a vaginal douche:

1. Use a fountain syringe, holding four gallons of water, with a four-foot head.
2. Begin with three quarts of boiled water at 103 degrees (married women).
3. Increase the heat 1 degree at each sitting until it is as hot as it can be borne.
4. Increase the amount of the douche one pint each time until four gallons are taken.
5. Use the douche in the morning, and in the evening when retiring.
6. The duration of a vaginal douche should be eight minutes to the gallon.
7. The patient should lie on the back with the thigh flexed on the abdomen and the legs flexed on the thighs.
8. The douche should be taken on a level plane, the ironing-board serving a good purpose, and not in the bed, or on the water-closet, or in the bath-tub.
9. The douche should never be taken in the standing or sitting posture.
10. A handful of salt (NaCl) and a teaspoonful of alum may be added to every gallon; the salt to prevent reaction and the alum to astringe and check waste by secretion.
11. The vaginal tube used in giving the douche should be sterilized and every patient should have her own tube.
12. A vaginal douche given according to the above directions will prove to be of much therapeutic value in the treatment of pelvic diseases, an agent to prevent disease and a great comfort to the patient.

The effect of a vaginal douche is: 1, to contract tissue, *i.e.*, muscle, connective, elastic; 2, to contract vessels, *i.e.*, arteries, veins, lymph; 3, to absorb exudates; 4, to relieve pain; 5, to check secretion; 6, to stimulate (tonic); 7, to cleanse parts.

A second form of medical treatment for metritis consists in the use of cotton (or wool) tampons soaked well in boroglycerid (glycerin, 16 ounces; boracic acid, 2 ounces). The tampon is distinctly hygroscopic and an excellent mechanical support; otherwise it has a similar effect with the vaginal douche. The tampon may be used three times a week and allowed to remain in the vagina for ten hours. With six months or more of such treatment the hypertrophic uterus is nearly always benefited and frequently so much improved that the patient is comfortable. Sometimes she is cured symptomatically or perfectly. Pregnancy often cures it perfectly. Painting the cervix with various materials is, so far as my observation goes, of very limited benefit.

The surgical treatment of metritis consists in dilatation, curettement and the application of a caustic, Alexander Adams' operation or hysterectomy. A fixed uterus should always be curetted with caution. Dilatation of a metritic uterus is accompanied with dangerous trauma. Some metritic walls are so thick that they can not be dilated and often vastly more damage than good is done to a metritic uterus by dilatation. The solid, metritic walls will not dilate without thousands of localities of trauma, which prepare the way for wider and more intense infection. Some may be curetted with a small curette without dilatation and endometrium cauterized, pure carbolic acid being one of the best caustics. However, from experiment with the curette on recently removed uteri, I am convinced the curette is not what accomplishes the good effect, but it is the applied caustic, the pure carbolic acid which sloughs off the old chronically inflamed endometritis and allows a new endometrium to appear, giving nature a chance to rejuvenate itself. I use a rubber tube stitched in the uterus to drain for a week, washing it out with alcohol and sterilized water from the third day on. Some use gauze, but gauze is a poor drain. It may be borne in mind that it is dangerous to curette a fixed metritic uterus and it is even more dangerous, from trauma, to dilate a thick-walled metritic uterus. Hence, the douche and tampon are often more successful than the dilator and curette in a large metritic uterus. The Alexander Adams' operation is often of value in the hypertrophic metritic uterus. Its upright position will allow vascular depletion. The hard ring and intrauterine stem pessary are a traumatic evil and are mentioned only to be, in general, condemned.

To say that metritis calls for hysterectomy to cure a patient, would doubtless call anathemas on my head from many physicians whom I respect. But I have cured absolutely, from metritis, so many patients by hysterectomy who were invalids for years previous, that I dare to follow the operation and abide by the result to tell its own simple story. Of course, only selected cases of metritis call for hysterectomy, after which patients get well and fat. I now nearly always remove the uterus when both appendages require removal. Dr. Lucy Waite and myself have now practiced the removal of the uterus with bilateral disease of the appendages for over three years and our satisfaction grows with improving results. The hard, solid, hypertrophic, metritic uterus can be sometimes cured only by extirpation; the safest route is per vaginam.

There is a significant question as to how far the frequent metritis enters into the etiology of uterine myomata. Doubtless many myomata are due to local disturbances in uterine circulation.

THE ETIOLOGY OF METRITIS INFECTION.

Kinds of infection: Gonococcus; streptococcus; staphylococcus.

Modes of entrance: Glandular; circulatory lesions; tissue.

Predisposing causes: Labor; abortion; lack of submucosa: menstruation: sexual irritation; the mucosa and muscularis do not move independently; traumatic lesion: vascularity; excess of lymphatic elements: muscular trauma on infected utricular glands.

Pathologic results: Deposit of connective tissue; hypertrophy; atrophy.

Clinical results: Pain: menstrual disturbance; sterility; hemorrhage: prolapse; reflex irritation.

The predisposition of the uterus, over other hollow organs, to inflammation is because the uterus has no submucosa and hence the mucosa and muscularis do not move independently as in the stomach. The utricular glands penetrate the muscularis directly and thus can be traumatized directly by muscular contractions and induce consequent direct infection.

100 State Street.

THE TECHNIQUE OF PIROGOFF'S AMPUTATION OF THE FOOT.

Presented to the Section on Surgery and Anatomy at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY GWILYM G. DAVIS, M.D., M.R.C.S., ENG.
SURGEON TO THE EPISCOPAL, ST. JOSEPH'S AND ORTHOPEDIC HOSPITALS, PHILADELPHIA.

Pirogoff was the celebrated Russian surgeon of the Crimean War. He was the surgeon in charge of the Russian forces at Sebastopol, and it was in 1852 that he devised his operation of osteoplastic amputation of the foot. His contemporary, Syme of Edinburgh, had not long previously given to the world his equally famous method of amputating the foot and, not unnaturally, in a clinical lecture on the subject (*Lancet*, Vol. I, 1855, p. 307), explained the superiority of his operation to that of Pirogoff. The only practical difference between the two operations was that Pirogoff retained a piece of calcaneum in the heel flap, while Syme dissected it out.

I have ventured to bring this operation to your notice because it appears to me to be one of great merit, particularly in cases of railroad injuries, and because the satisfaction to be derived from it will depend largely on the manner in which it is performed.

Judging from a long period of observation of the operation, as done on the cadaver in classes in operative surgery, and also as done on the living body, it is apt to be both a tedious and slovenly performance, and the subsequent results to the living are not so good as would be the case had more care been bestowed on its doing.

Pirogoff's original communication appeared in his work entitled "Klinische Chirurgie: Eine Sammlung von Monographien, über die wichtigsten Gegenstände der praktische Chirurgie," Leipzig, 1854. It is rarely alluded to; even he himself in his work on military surgery does not state where he published it. Fortunately, T. Spencer Wells (*Medical Times and Gazette*, March 20, 1858, p. 288) gives a translation of the original article. Pirogoff's own description is given by Wells as follows: "I commence my incision close in front of the outer malleolus, carry it vertically downward to the sole of the foot, then transversely across the sole, and lastly obliquely upward to the inner malleolus, where I terminate it a couple of lines anterior to the malleolus. Thus all the soft parts are divided at once quite down to the os calcis. I now connect the outer and inner extremity of this first incision by a second semilunar incision, the convexity of which looks forward, carried a few lines anterior to the tibio-tarsal articulation. I cut through all the soft parts at once down to the bones, and then proceed to open the joint from the front, cutting through the lateral ligaments, and thus exarticulate the head of the astragalus. I now place a small narrow amputating saw obliquely upon the os calcis behind the astragalus, exactly upon the sustentaculum tali, and saw through the os calcis so that the saw passes into the first incision through the soft parts. Saw carefully, or the anterior surface of the tendo Achillis, which is only covered by a layer of fat and a thin fibrous sheath, might be injured." "Lastly," says Pirogoff, "I separate the short anterior flap from the two malleoli, and saw through them at the same time close to their base. I turn this flap forward, and bring the cut surface of the os calcis in apposition with the anterior surface of the tibia. If the latter be diseased it is sometimes necessary to saw off from it a thin slice with the malleoli." This translation is almost exactly as given by Sedillot ("Contributions à la Chirurgie," Vol. II, p. 194), where Pirogoff's entire article can be found in French.

The principal change suggested in the operation was either by Dr. Eben Watson, Surgeon in the Royal Infirmary of Glasgow, and published in the *Lancet* of June 11, 1859, or by William Pirrie, Professor of Surgery in the University of Aberdeen, and published in the later editions of his "Surgery," or perhaps by both independently. It consisted in making the incision from the tip of one malleolus across the sole of the foot to the other, then sawing through the calcaneum upward and backward. The incision is prolonged up behind the ankle joint and carried across the front to the opposite side. The leg bones are then sawn through just above the ankle joint. Watson advised that the section of the leg bones be made downward and forward, but all other operators have recommended that more of the posterior edge should be removed.

The technique now suggested is as follows, the left foot being the one to be operated on: The foot resting on its outer side, sink the knife into the tissues of the sole and side of the heel, down to bone, on a line with the posterior edge of the internal malleolus, and prolong the incision directly upward to the upper edge of the swell of the ankle; this will be about three centimeters, or an inch and an eighth above the tip of the malleolus. Turn the foot on its inner side and, grasping the heel with the left hand, continue the incision across the sole of the foot and up the outer side along the posterior edge of the external malleolus and fibula until it reaches a point opposite to the ending of the first incision. The foot, resting on its heel is now firmly extended and the two ends of the side incisions joined by another curved one, forming an anterior flap one inch in length. This is turned back, and by a touch of the knife on each side the tissues are separated from the posterior surface of the bones sufficiently to allow the passage of a director or other instrument to prevent the tissues being injured by the saw. The leg bones are now sawn through just above the swell of the ankle, the posterior flap separated downward by a few strokes of the knife and the calcaneum sawn through in the line of the skin incision. The projecting outer corner of the fibula is removed, and the fragment of the calcaneum is to be brought upward, fastened securely to the tibia by means of chromicized catgut passed through holes in the bones, and the skin wound closed by interrupted sutures without drainage.

The incision across the sole of the foot is placed farther back than is that of Pirogoff, or of Watson's or Pirrie's modification. In them, in order to divide the calcaneum it is necessary to place the saw so far behind the line of incision that the flap will be torn unless it is retracted. It is to avoid this that Treves, Agnew and others have advised that the heel flap be dissected back a quarter of an inch or more. It is difficult and troublesome to saw the bone under these conditions, and is not required if the two ends of the plantar incision are carried along the posterior edges of the malleoli. Placing the incision so far back does not endanger the artery, for the two are still separated by the tendons of the tibialis posticus and flexor longus digitorum.

The plantar incision is prolonged upward to the upper edge of the swell of the ankle, in order to allow of a high section of the bones. The anterior flap is made an inch long, in order to allow for the retraction which takes place consequent on making the incision while the foot is in an extended position. The bones are sawn through at a higher level than usual, in order to make a thinner and shorter stump. This reduces the difference in width between the two ankles when an artificial foot is worn, and renders the deformity less conspicuous. It also raises the stump sufficiently to allow of a cylindric joint being used instead of two side joints, thus adding to the strength and durability of the appliance. By making the section of the bones in the manner described, an ordinary amputation saw can be used in the usual manner. It is not necessary to use a small saw with a movable back as advised by Heath, nor a small narrow saw as did Pirogoff, nor a Butcher's saw as recommended by others.

The high section of the leg bones always allows the heel flaps to be brought up into position without any tension on the tendo Achillis. To avoid and remove any tension on the tendo Achillis, Pirogoff advised removing, if necessary, an additional slice from the tibia. Sedillot, Busk and Günther advised an oblique section of the bones. Sir William Ferguson ("Practical Surgery,' p. 427) advised section of the tendon for the same reason. He said: "I am so satisfied of the advantage of dividing the tendo Achillis in this operation that I recommend it as a preliminary step, to be performed much as in a case of talipes." Agnew also (Vol. II, p. 360) advised its division in case the bone did not readily come into place. Addinell Hewson, Sr. (*American Journal of the Medical Sciences*, 1864, II, p. 121), to whom we largely owe the popularization of this operation in this city and country, was accustomed to apply a broad piece of adhesive plaster to the back of the leg to prevent the calf muscles from drawing the calcaneum up. These facts are sufficient evidence that inability to approximate the sawn bones is of frequent occurrence in this operation as usually performed.

Mr. Jacobson, in his "Operative Surgery," advises fastening the calcaneum to the tibia with chromic catgut or silver wire. This I have made a practice of doing, preferring the chromic catgut. It prevents displacement and insures better and quicker union of the bones.

Removal of the foot by sawing the bones instead of disarticulating, originally suggested by Watson or Pirrie, adds greatly to the ease and quickness of the operation. A high section of the leg bones obviates the necessity of clearing the malleoli of the soft tissues for the application of the saw.

In the performance of the operation as here described, it can be done easily and quickly; the foot can be removed without undue haste in less than three minutes; no difficulty is experienced in the application of the saw; the edges of the flaps are not lacerated by it; the bone comes readily into place; and the resulting stump is the best possible for a serviceable and artistic artificial appliance.

255 S. Sixteenth Street.

Menthol Collodion for Contusions is recommended by Namé to soothe pain and accelerate recovery. After rigorous antisepsis and cleansing of the contused parts with ether, they are painted once or twice a day with a mixture of 21 to 27 grams of collodion with 6 to 8 grams of menthol.—*Journal de M. de P.*, September 12.

MORBUS COXARIUS, EXSECTION.

Presented to the Section on Surgery and Anatomy at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY JAMES W. COKENOWER, A.M., M.D.

SECRETARY IOWA STATE MEDICAL SOCIETY; LECTURER ON ORTHOPEDIC SURGERY, COLLEGE OF PHYSICIANS AND SURGEONS, MEDICAL DEPARTMENT OF DRAKE UNIVERSITY.

DES MOINES, IOWA.

It is not the purpose of this paper to catalogue the views of authors on the subject, for the consensus of evidence is strongly in favor of the osseous origin in children, while in adults synovitis is more common; and the former usually originate in osteomyelitis of the end of the bone, while the latter commences in the synovial membrane A majority of authors believe the disease to be invariably the result of a contaminated constitution and essentially strumous in its origin, while a few others claim traumatism as the cause and cite cases that have gone through the different stages of the disease, with anchylosed joint, but lived to a vigorous, robust old age; when if every case had been tubercular, or of a strumatic diathesis, this could not be. I believe many latent cases of coxarius, which might never have been manifested, have been so by traumatism and have passed through the different stages; thereby with disastrous results. I do not believe, however, the disease ever begins in the cartilages of the joint, because they contain neither blood vessels nor nerves, and necrosis occurs secondarily in the cartilages, on account of the loss of nervous and vascular supply to the tissues which they depend upon for nutrition. It is not so necessary to know the exact origin and location of the disease as it is to know the best and quickest means to overcome it from what we do know and leave the patient in the best possible condition, and to that end I will give a brief outline of the treatment which has proven most satisfactory in my hands.

The first thing to be done after immobilization of the joint and limb is to remove the pressure from the former by extension and counter extension, not in a line of the normal axis of the limb, but in the line of the deformity, augmented by lateral traction, which will better serve to take the pressure from the intra-articular membranes; which is not wholly for the purpose of remedying the deformity that may exist at that time, but to retard and prohibit, if possible, the destruction of tissue, that whatever deformity then existing may not be increased. The idea that convalescence should be interfered with simply because we wish to have no deformity, is not feasible, much less plausible, when it is easy to correct most deformities after permanent convalescence, all things being equal, and a recovery can be accomplished without any deformity it is much more preferable; but I believe if we were to give less attention to the deformity while the ravages of the disease are active and simply supplement nature in her efforts to protect we would get better results. But as it is not convenient for us to select our cases and many present themselves to us with existing deformity and acute symptoms of the disease still present it is not best to correct the deformity in such cases, for if force were employed it might exaggerate *the disease and develop* an abscess in some deep inaccessible part. After all that is possible has been done by means of extension, counter extension and lateral traction, and in my opinion one pound of the latter is worth five of the former, then comes the local treatment, which if too conservative will cause the patient to risk his life in the hope that absorption and elimination will come to the rescue; so the best way would be to treat all abscesses or sinuses by cleaning out, curetting, asepticizing and drainage; but all these are secondary to the real trouble and are but symptoms, the lesion being in the bone no matter whether this be pure or mixed tuberculosis, or staphylococcus abscess. There was no object in any operative work that did not aim to remove the focus in the bone, nor was there any local treatment that did not strive to accomplish the same, and when this fails I have no hesitancy in performing osteotomy or excision.

Report of case.—A. B., aged 9 years, had hip disease for over a year, the supposed cause being a slight injury received while recovering from an attack of typhoid fever. The case was first brought to my notice Jan. 10, 1896, and presented the usual appearance of third-stage hip disease, the leg and thigh *being well drawn up and adducted across the other thigh.* Several sinuses existed, through which the crepitous dead bone could be reached; a free incision over the trochanter major united the sinuses, which were curetted and cleaned out, and from the condition of the continuity of the joint I concluded that exsection was the proper thing to do. After preparing the field of operation, the head of the femur was luxated and sawed off at trochanter minor and several pieces of bone were removed from the acetabulum and the whole of the denuded surfaces thoroughly curetted and aseptically dressed and, for the want of anything better, the patient was put on a wooden substitute for "wire breeches," with the limb in normal position, with extension and counter traction. The patient began at once to improve and continued to do so, the wound healed nicely and in four months the boy began to walk, with the assistance of crutches. Passive motion was gradually made. In six months he dispensed with crutches and could get around as nimbly as most boys, having good motion and but one inch shortening.

I believe, as Dr. Phelps of New York said, in 1895, at Washington: "We are all endeavoring to avoid excision, yet there are cases where the demand is imperative." The percentage of deaths in exsection of the hip joint is so low and the subsequent usefulness of the limb so satisfactory that I am of the opinion that we should not hesitate to operate upon all cases that need it and never permit a limb to anchylose in any position, except that which will render it the most useful.

THE SUCCESSFUL TREATMENT OF SNAKE BITE.

BY J. G. TUTEN, M.D.

JESUP, GA.

June 1, 1896. M. O., aged 26 years, was bitten by a rattlesnake inside of gastrocnemius muscle of right leg four hours before we saw him. We found the patient suffering a great deal of pain and leg very much swollen; pulse rate 130 and very weak; respiration 48 and very much labored. The leg was very well corded in two places, one below and one above knee. I immediately made an incision two inches long at the place where the fangs entered, then a cross incision two inches long and then a circular incision, taking in the whole of the skin and muscle an inch all around where the fangs entered; then I poured in about two drachms of crude carbolic acid and about two drachms of permanganate of potash in crystals. I then gave him, hypodermically, one grain of *permanganate of* potash every hour for thirty-six hours and an ounce of alcohol every two hours for thirty six hours.

As soon as I gave the first potash hypodermically I put on an Esmarch bandage, commencing at the toe and putting it up to the wound. I put it on tight because the leg was very much swollen and I wanted to press out as much blood as possible at the opening cut by me. I also put on a bandage around the leg above the wound, and below tourniquet with a man at each end and made them keep the bandage tight so as to squeeze out all the blood possible.

June 2. At 7 A.M. the record showed: *No stools, no sleep,* urine, almost no pulse, respirations about 60. At 6 *o'clock he* began to sink. No radial pulse and only faint heart sounds in cardiac region. In state of collapse. I then gave 15 gtt. tr. digitalis every two hours and 20 m. pure undiluted alcohol in twelve or fifteen different places as fast as I could give them hypodermically, and 1 grain of permanganate of potash every hour. By 8 o'clock A.M. it looked as if he would die at any moment. He was suffering a great deal of pain and the chances were so small that I released the two tourniquets and in a short time he was resting some better, but respirations were increased to very hurried panting. I kept up potash, digitalis and pure alcohol hypodermically all day and also put a tobacco poultice over the wound, as suggested by Dr. G. W. Drawdy, but do not think it did any good. The patient remained in this collapsed condition until about 7 o'clock on the morning of June 3.

June 3. At 7 A.M. the radial pulse began to reappear, although but very small and thready, but it grew steadily stronger until it could be counted by 6 P.M., when it beat 130 times to the minute. Respirations began to get slower at 7 A.M. and gradually grew slower, until by the night of June 3 they were about 30 to the minute. At 9 A.M. we gave a large enema, when the bowels moved freely; continued the potash every two hours and digitalis fifteen drops every four hours. Digitalis was given by the mouth, also one ounce of alcohol four or five times every twenty-four hours. The region around the bite on the leg began to bleb up and filled up with dark sanguinous fluid, while the skin began to look gangrenous.

June 4. The record showed: Milk diet, two stools, some sleep, free urine, pulse 120, temperature 100 degrees, respirations 25. The potash was discontinued but alcohol every four hours, alternating with the above dose of digitalis every four hours was continued. He continued to grow stronger. The leg around the bite continued to get darker, embracing the inside of the calf and whole calf of leg from two inches below knee on inside to one inch below and around ankle. Foot swollen but dark in spots, but on the outside of the calf there extended a healthy section of skin about two inches wide in the lower one-third of the leg, which grew wider from there, when at the ankle the whole foot except around the inside of the ankle looked somewhat healthy.

June 5. Milk diet, stools twice, some sleep, free urine, pulse 110, temperature 99.5 degrees, respirations 24, alcohol every 4 hours, digitalis every four hours. The leg in the above described place was still darker, in fact was black. The line of demarcation was formed, extending from two inches below the knee down just to inside of the shinbone down to and one inch below the ankle, coming back up one-half inch behind the ankle, and when one and one-half inches above ankle behind, it began to spread wider, taking in the whole calf, and only lacking about two inches from meeting around on the outside of the leg. The extreme length was thirteen and one half inches and breadth eight and one-half inches. *This* whole surface afterward sloughed off.

June 6. Milk diet, several stools, some sleep, urine very free, pulse 108, temperature 99, respirations 23, alcohol and digitalis as above. The gangrenous parts began to slough off.

June 7. Milk diet, several stools, some sleep, free urine, pulse 108, temperature 99 degrees, respirations 23; alcohol and digitalis continued as above; the gangrenous parts still sloughing.

June 8. Milk diet, stools very free, some sleep, free urine, pulse 108, temperature 99 degrees, respirations 32; alcohol and digitalis as above; sloughing very free all around where the fangs entered, the bite being in the center of the slough. Carbolized sweet oil is being used on the slough, strength 1 to 32.

June 10. Milk diet, stools very free, some sleep, free urine, pulse 108, temperature 99 degrees, respirations 22; digitalis every four hours as a stimulant, alcohol being discarded from this date; 20 grains sub. nit. bis. for the watery diarrhea every three hours; slough almost complete and dressed with carbolized sweet oil, 1 to 32.

June 12. Milk diet stools very free, some sleep, free urine, pulse 108, temperature 98.5 degrees, respiration 21; the bismuth was continued and lead and opium pills added, opium 1 gr. and lead ½ gr. to pill, one every four hours alternating with bismuth. This controlled the bowels from this on, *i. e.*, while taking pills and bismuth, but as soon as left off the bowels would run again, so had to keep it up for about three weeks longer. Slough complete and dressed twice daily with 1 to 32 carbolized sweet oil.

June 14. Milk, grist and butter, three or four stools, seven hours sleep, free urine, pulse 104, temperature 98.5 degrees, respirations 20; digitalis, bismuth, lead and pills (opium); leg dressed twice daily with carbolized solution.

June 16. Regular diet, two to three stools, eight hours sleep, free urine, pulse 100, temperature 98.5 degrees, respirations 20; treatment continued as above.

June 18. Regular diet, two to three stools, eight hours sleep, free urine, pulse 100, temperature 98.5, respirations 20; treatment as above.

June 21. Regular diet, one to two stools, eight hours sleep, free urine, pulse 100, temperature 98.5, respirations 20; treatment as above. All around edges of slough beginning to granulate and healing from all sides. Slough only took off skin and fasciæ and part of muscle in only one place, and that was directly underneath where the fangs entered.

June 24. Regular diet, one to two stools, eight hours sleep, free urine, pulse 100, temperature 98.5 degress, respirations 20; treatment continued as above and slough healing rapidly. We wanted to skin graft, but the patient would not agree to it. Where we used pure alcohol hypodermically each place on the arms and leg has sloughed a place as large as a silver dollar. These sloughs are dressed same as leg.

June 28. Regular diet, one to two stools, eight hours sleep, free urine, pulse 100, temperature 98.5 degrees, respirations 20; treatment same as above; all sloughs healing rapidly.

July 2. Regular diet, one to two stools, eight hours sleep, free urine, pulse 100, temperature 98.5 degrees, respirations 19; treatment as above; sloughs healing rapidly.

July 9. Regular diet, one to two stools, eight hours sleep, free urine, pulse 100, temperature 98.5 degrees, respirations 19; treatment same as above; sloughs healing rapidly.

July 17. Regular diet, one to two stools, eight hours sleep, free urine, pulse 100, temperature 98.5 degrees, respirations 18; treatment same as above; slough healing rapidly. I never saw him again until August 26, when slough was more than half healed, it then being eight inches long and three and one-half inches wide. He was having intermittent fever. I gave quinin and arsenic, which broke it up at once.

March 5, 1897. The first time I have seen the patient since last August. There is still a sore one-half inch wide and three inches long, with foot swollen and leg flexed toward thigh. I advised silk elastic stocking to relieve the swelling caused from varicose veins, but the patient would not consent.

April 25. Sore same size, foot swollen, leg flexed. He consented to use silk stocking, which was put on immediately.

May 15. Raw surface almost well, swelling in foot gone and leg not near so much flexed on thigh.

I believe the permanganate of potash to be the sheet anchor, combined with alcohol and digitalis. I also know that free incisions and free bleeding from bitten parts are very necessary, and the tourniquet must never be forgotten. I would say tourniquet first, free incisions second, permanganate of potash third, Esmarch's bandage fourth, alcohol and digitalis last.

THE PHYSIOLOGY AND THERAPEUTICS OF THE THYROID GLAND AND ITS CONGENERS.

BY H. GIDEON WELLS, PH.B.
CHICAGO, ILL.

(Awarded the L. C. P. Freer medal, Rush Medical College, 1897.)

From the chemic and pathologic laboratories of Rush Medical College.

The use of the thyroid gland as a remedial agent, while one of the latest advances in therapeutics, is at the same time one of the most striking examples of the success of rational and experimental methods in therapeutics that can be cited. Its general use began but six years ago, yet within that time it has made its way to the highest rank assigned to therapeutic materials—the specific drugs. That the thyroid extract is as surely a specific in its own field as are quinin, iron and the iodids in theirs, can not be doubted when we consider the manner in which the cretin, after receiving a few tablets, shakes off its lethargy of mind and loses its repulsiveness of figure to become an actually different being; or the way the characteristic symptoms of myxedema vanish under this form of treatment

In the ascendancy of the thyroid extract to its deserved position as a therapeutic resource it has been obliged to drag with it many other preparations which, although older in their conception, are based on entirely different grounds (the doctrine of *similia similibus*, in fact), and which association has been one of the greatest obstacles to its general use. This refers to the host of preparations commonly classed as "the animal extracts," including such articles as cerebrin, testin, ovarin. nephrin, etc., the list of one London firm containing twenty-one such preparations, including practically every organ and tissue in the body. All of them owe their presence on the market chiefly to the phenomenal success of the thyroid extract, and yet none of them, excepting possibly the extract of bone marrow and of the thymus gland, can show well authenticated clinical results that entitle them to existence. They originated with the exploded theory of Brown-Séquard that impotence could be cured by the ingestion of testicles, and would now be merely historic but for the great success of a drug belonging to the same class by the fact of its being an animal product.

The use of the thyroid gland in medicine was gradually acquired and grew step by step with our knowledge of its physiology and pathology. Up to the year 1883 nothing was known of the importance of the thyroid gland in the animal economy. Previous to that time its function was set down in the textbooks as rounding out the neck, having some influence on the voice or being concerned in the production of sleep. To be sure, in 1859 Schiff[1] had reported that extirpation of the thyroid gland in dogs resulted fatally, but this fact seemed to be entirely overlooked until, in 1883, J. and A. Reverdin described the changes occurring after the removal of the thyroid gland for goiter, and identified them with the symptoms of myxedema. Previous to that time (1878), Ord had discovered that this disease bore a relation to the thyroid gland. Kocher soon followed the Reverdins with reports of many cases of operative myxedema, observing that the symptoms were most marked in young subjects. These reports caused Schiff to repeat his previous experiments, and in 1884 he reported that extirpation of the thyroid gland was not only followed by death preceded by spasms, convulsions, etc., but that this result was entirely prevented if the extirpated thyroid were implanted into the skin or peritoneal cavity of the animal. Horsley followed with experiments on monkeys, which, living longer than did the carnivora, developed a typical myxedematous condition. Later, von Eiselberg showed experimentally the relation of the thyroid to cretinism by removing the gland from newborn animals, which then developed a cretinoid condition.

The results of the implantation experiments of Schiff naturally led to the adoption of analogous procedures in human beings, and Bircher, in 1890, successfully implanted a human thyroid twice in a woman with cachexia strumipriva. At about the same time Horsley suggested the propriety of implanting the sheep's thyroid gland in cases of myxedema and cretinism. Bettencourt and Serrano, following this plan, implanted one-half of a sheep's thyroid in the inframammary region on each side of a woman suffering with myxedema, and noticed an improvement within twenty-four hours. As this improvement took place before vascularization could have begun, they suggested that it might be due to absorption of the juices escaping from the gland.

Working on this basis Murray, in the same year, made the announcement that glycerin extracts of the gland, which were rendered aseptic by the addition of carbolic acid, when injected subcutaneously, produced marvelous results in a case of myxedema. From this report practically dates the therapeutic use of the thyroid gland, for this method was immediately adopted universally, and soon great numbers of cases corroborating Murray's results were reported. However, the objections to the use of the extract hypodermatically were many, and in 1892 Mackenzie and Fox independently reported that they had obtained fully as good results by administration either of the glycerin extract or the thyroid gland itself by mouth.

From its history, therefore, it is evident that the use of the thyroid gland has in every instance been based upon reliable results of scientific research, and must be considered as entirely separate from the bulk of the "animal extracts" which have no such ground for their use. The marvelous changes produced in myxedema have caused the thyroid extract to be used in nearly every skin lesion imaginable, but these applications have been mainly in the line of experiment and have in most instances been discontinued; and the same can be said of its administration in nervous diseases. But the over-wide use of every drug with a positive but limited utility is invariable, and can in no wise detract from its reputation in its own proper fields.

Before describing the physiology and therapeutic uses of the thyroid it is necessary first to consider its structure and chemic composition, since on these depends much of our knowledge of the organ, and it is along the lines of chemistry that the most important discoveries have been made.

Anatomy.—The thyroid gland consists of two lateral lobes, generally connected by an isthmus which lies across the trachea from the second to the fourth ring, the lateral lobes extending above and slightly below this level on each side. It is attached behind to the larynx and trachea by tough fibrous tissue, and in front to the depressores hyoides muscles. The isthmus is sometimes wanting—Marshall found it present in 90 per cent. of a series of sixty cases, and the writer in a series of the same size has found it present fifty-two times, or 87 per cent. In one of these cases the isthmus existed as an isolated, cherry-sized mass between the two lobes, but entirely distinct from them, and with a separate pyramid connecting it with the thyroid cartilage. This mass was in structure identical with the rest of the gland and, as will be seen later, very nicely shows the manner of development of the thyroid. The isthmus varied greatly in size, sometimes as thick and large as the lateral lobes, at others but a thin cord of glandular tissue.

Frequently a conical process, called the "pyramid of Lalouette," extends upward to be attached to the hyoid bone, thyroid cartilage, or thyro-hyoid membrane. This may arise from the isthmus or from either or both lateral lobes, its shape and size also presenting wide variations. Its frequency varies greatly according to different observers. Marshall found it in twenty-six out of sixty cases or 43 per cent.; Streckeisen in 101 out of 153 cases; Zoja in 109 out of 147 or 74 per cent.; while the writer, by careful dissection of sixty thyroids, found the pyramid thirty-six times or 60 per cent. In ten cases it arose from the right lobe, in twelve from the left, in eight from the isthmus, in five from both lobes, and in one from the left lobe and from the isthmus. In twenty-one cases it was attached to the thyroid cartilage or thyro-hyoid membrane, and to the hyoid bone in fifteen. In one case the pyramid was split up into a chain of isolated masses of gland tissue, which would have to be classified as accessory thyroids. In structure the pyramid generally consists of regular gland tissue near its base, but the colloid material disappears as it ascends, and the vesicles become mere groups of epithelial cells which are gradually replaced by fibrous and muscular tissue, until, near the upper part of the pyramid, they disappear entirely. If the muscle fibers are numerous the upper part of the pyramid is considered as a separate muscle, and called the levator glandulæ thyroidæ. The pyramids are considered by Bland Sutton as representing part of the orignal thyro-glossal duct.

---

[1] The authors and papers referred to will be found grouped alphabetically at the end of this article.

Accessory thyroids are frequently formed by detachment of small portions of the gland during its embryonic history, often by division of the pyramidal processes as in the case described. The accessory thyroids may be found anywhere between the arch of the aorta, where they are especially numerous, and the thyroid bone. Cases have been reported where they were found in the substance of the os hyoides itself.

The para-thyroids are two small bodies, first described by Sandstrom, which lie close to the lateral lobes. Kohn has described them as consisting of two pairs, an "outer epithelial body" which lies on the lateral surface, and the "inner epithelial body" on the mesial surface of each lateral lobe.

The weight of the thyroid would seem to vary greatly in different countries; since most German authors (Virchow, Rauber) place it at from 30 to 60 grams; Schäfer in England gives it as 30 to 40 grams, while the average weight of sixty glands removed from residents of this city was but 22 grams. The gland atrophies greatly in old age. In this series the gland in persons over 45 years of age was but 16 gms., while in people between 20 and 45 years it averaged 25 gms.

The thyroid is developed from two sources. 1. A median diverticulum of the pharyngeal hypoblast pushes its way downward, and forms a tube which is connected to the base of the tongue. Subsequently it becomes solid, its upper end forming the foramen cecum, from its lower end developing the isthmus, part of the lateral lobes, the pyramids of Lalouette (when they are present), and occasionally accessory thyroids. It sometimes happens that this structure remains in the adult as the "ductus lingualis." 2. From the fourth visceral cleft on each side spring pouches which pass in front of the larynx and unite with the lower end of the median diverticulum, ultimately forming the outer part of the lateral lobes.

The manner of formation of the thyroid gland explains completely its great variations in shape, and especially is this variation permitted by the fact that unlike most of the parenchymatous organs the location of its secreting structures bears no relation to any fixed outlet or duct, which arrangement must necessitate a certain limit to irregularity.

At first the gland merely consists of rod-like columns of epithelial cells, resulting from the division and branching of its original rudiments. As colloid material is formed, the walls are pushed aside, and at some time in the period of development the original continuous tubes become divided up into vesicles. The colloid formation begins in intra-uterine life, but the vesicles are not generally filled until some time after birth, section of the gland of a new-born child showing but few of the acini containing colloid.

In the adult the vesicles are found to be of many sizes, some distended with colloid so that their epithelium is flattened out until it resembles endothelium, others containing not a trace of colloid and consisting merely of tubes lined with columnar epithelium, which may in case of necessity become filled with colloid and converted into true follicles. They are separated by a stroma derived from the capsule of the gland, which sends in trabeculæ that break up into finer and finer divisions until they ultimately separate the individual follicles, and also form their basement membrane.

The epithelium of the thyroid is divided in three classes, which are described by Bozzi as follows:

1. Chief cells (*Hauptzellen*).—These are the most numerous. They contain bodies strongly refractive and apparently identical with the colloid material, which can be best seen when the cell is in unusual activity, as when a large portion of the gland has been removed. Many still finer bodies can be seen, which Bozzi thinks are incompletely formed colloid, although Babers and others have considered them as pigment from destroyed red blood corpuscles. Fat globules and protoplasm granules are also present. There seems to be no distinct membrane surrounding the cells, which blend with one another, their outer ends resting on the basement membrane, the inner ends lying in the colloid substance.

2. Colloid cells.—Small, low cells found in varying numbers in the different follicles. They lie scattered in groups between the chief cells, from which they are derived. They possess a more homogeneous protoplasm which is colored more intensely, somewhat resembling the colloid substance. Some preserve the form of the chief cells, others are round or oval, and the protoplasm almost destroyed or collected in a ring about the central mass which resembles colloid substance and contains characteristic vacuoles, the nucleus being pushed to one side. They often group together so as to resemble follicles, and sometimes free colloid substance is found between the cells. It is probable that the colloid cells of the first class may again become *hauptzellen*; but those of the second class whose nucleus and protoplasm are completely destroyed, probably can not. It is probable they are formed by an accumulation of colloid in the cell which can not escape because of some alteration in the cell membrane.

3. Cells undergoing retrograde metamorphosis.—These do not show accumulations of colloid. The alterations begin in the nucleus, which loses its power to retain stains, while its outline becomes less and less distinct. In the protoplasm the granules become smaller, the drops of colloid do not run together but remain long separate. The cell outline remains distinct until after all traces of the cell are lost. These forms are found where a fusion between adjacent follicles occurs and seem to be due to shutting off of nourishment.

Embryonal rests are found, especially under the capsule, but often in the gland substance itself. The cells lie without order in a connective tissue stroma, and have large, chromatin-rich nuclei and little protoplasm. Bozzi has found no alterations in embryonal rests left in small stumps of gland tissue remaining after removing the greater part of the gland, nor did their presence prevent the death of the animal.

The accessory thyroids are identical in structure with the thyroid gland itself, and are capable of hypertrophying and performing the functions of that organ when it is removed, if they be sufficient in their total volume.

The para-thyroids are composed of columns of epithelial cells, with large, deeply staining nuclei, and a rather small amount of protoplasm. They are packed closely together, separated by a stroma composed chiefly of small blood vessels, the connective tissue being very scanty. They closely resemble the carotid glands in structure, but the thyroid not at all, and it is considered by Prenant that they are derived from the fourth inner branchial cleft from which the thymus and the lateral rudiments of the thyroid are also derived. Gley believed that they represented embryonic rudiments of the thyroid and were capable of hypertrophying under necessity to take up the function of gland, and even to develop into the same structure, but these ideas have not received confirmation from more recent observers.

The thyroid receives a rich blood supply from the superior and inferior thyroid arteries, which, following the trabeculæ, break up into a meshwork of capillaries surrounding the vesicles. These capillaries in some places even penetrate the basement membrane and come in direct contact with the secreting cells. The vascularity is so great that when an active dilatation of its vessels occurs the gland increases noticeably in size, and in this condition a distinct pulsation can be felt throughout the gland. Some authors have described collections of a colloid-like substance in the veins of the gland, and suggested that this was the method by which the gland disposed of its secretion, *i.e.*, directly into the circulation. However, these appearances are probably due to accidental extravasations occurring in the handling of the gland.

There seems to be no room for doubt that the excretion of the colloid material occurs through the lymph channels, which are very numerous in the thyroid and lie in direct contact with the basement membrane of the vesicles, sometimes even with cells themselves. In their lumen, the colloid is constantly to be found, presenting all the microscopic characteristics of this material. The routes by which it reached the lumen have been for a long time in question, but Bozzi, after a study of glands thrown into a hyperactive condition, has come to the conclusion that there are three ways in which this is accomplished. He removed a large part of the thyroid gland from dogs, and then studied the stumps left in the animal for several days, which were in a state of compensatory activity, and observed the colloid material to escape as follows:

1. Sometimes the epithelium directly over a lymph vessel, where the tension is greatest because of the lack of support from behind, becomes lower and its nucleus grows smaller. The connective tissue forming the basement membrane atrophies and disappears, so that the epithelial cells become poorly nourished until they can no longer stand the intra-vesicular tension, when the colloid breaks out into the lymph channel.

2. The epithelium may become very low but without change in the nucleus, and the cells over a lymph vessel separate until only the thin basement membrane is left between it and the contents of the follicle. This membrane soon ruptures and the colloid reaches the lymph stream, in this case without loss of epithelial elements.

3. The epithelial cells may play a passive role, the colloid material being driven by pressure between the cells until it reaches the basement membrane, through which it makes its way to be taken up by the lymph capillaries.

Probably the follicle discharges only the excess of its contents when the neighboring follicles by their elasticity crowd upon its walls so that the opening becomes closed, this process being repeated whenever the intra-vesicular tension exceeds the resistance of the walls.

The contents of the follicles, even in the same gland, vary greatly. In the colloid substance itself are generally found vacuoles, of which most are probably the result of shrinkage in the hardening fluids, although in some cases they may be due to the dropping out of the contents of the follicles, at all events they are probably not present in the follicles during life. Often the refraction of the central portion of the colloid material, as well as its stain-retaining capacity, may differ from that of the periphery, so that concentric zones are formed, not unlike the corpora amylacea of the prostate in appearance. Imbedded in the colloid, one may also find epithelial cells in different stages of degeneration, especially in follicles that have united with their neighbors by destruction of the septum between them; crystals of varying size and forms; fat globules; vacuoles containing a mass of fragments staining with hematoxylin, more closely resembling minute threads of mucin than anything else and which may be derived from the breaking down of epithelial cells, or even of the colloid itself; and in very many cases numbers of red blood corpuscles in all stages of degeneration, this appearance having given rise to the theory that the thyroid was an organ concerned in the destruction of red blood corpuscles. The colloid substance itself stains red with von Gieson's acid fuchsin stain, which is said to be characteristic of this material. It also stains yellow with picric acid, and a faint pink with eosin.

The glandular structure of the thyroid is capable of great hypertrophy, which is generally compensatory, although similar changes may occur in certain forms of goiter. Halsted has performed very many experiments to ascertain the nature of this hypertrophy. He finds that it does not generally occur, in dogs at least, until after more than one-half of the gland has been removed. The vesicles then lose their circular outline, become elongated and branched, or else the outline of the walls become very irregular, with papillary processes separating sacculated recesses. The colloid material at first becomes vacuolated and shrinks, so that the walls of the vesicle are not in their usual distended condition. It gradually becomes less solid and the quantity diminishes until many alveoli contain none at all. Apparently, from lack of tension, the epithelial cells become taller and more columnar, until, combined with the changes in the outline of the walls, they may nearly fill in the entire lumen. While pursuing these studies he often observed parathyroid bodies, imbedded in hypertrophic portions of the gland, which seemed in no way affected.

Chemistry.—Since the thyroid is an organ of internal secretion it was naturally believed that by analysis of the gland itself could be found the substances produced by its secreting cells, and which were the agents by which it produced its effects. It has long been known that it contains considerable quantities of extractives, chief among them being xanthin, hypoxanthin, kreatin, kreatinin and paralactic acid, which indicate a high degree of metabolic activity, but which could not well be the cause of its specific action. Many attempts to isolate this "active principle" were made with the idea that it was a ferment, and White and Davies obtained in this way a body that seemed to have some physiologic activity. Gourlay, working along the same lines, failed to find a ferment that would dissolve mucin, such as had been thought must be produced by the thyroid, but succeeded in isolating a nucleo-albumin which produced an intravascular clotting and which he believed was contained in the colloid. Bubnow extracted three different forms of proteid, one of them apparently a globulin, which was later isolated by Notkin, who believed that it was the toxic product of general metabolism which underwent decomposition in the thyroid gland, through the action of an enzyme therein produced.

Sigmund Fraenkel reported in the latter part of 1895, that he had isolated the active constituent in the form of a crystalline, alkaloid-like body, apparently belonging to the guanidin series and having the empirical formula $C_6H_{11}N_3O_5$. Drechsel subsequently described a body identical with that of Fraenkel which has been called "thyreo-antitoxin," and another similar to it. This thyreo-antitoxin, Fraenkel describes as a hygroscopic, crystalline substance, soluble in water and alcohol, the solution being neutral or slightly alkaline, and giving the reactions for alkaloids. Injected into animals it failed to produce an increased blood pressure but increased the pulse rate, and produced an improvement in thyroidectomized animals, which was however but temporary. While the activity of this substance can not as yet be absolutely denied, still many other observers have failed to verify Fraenkel's results.

This report of Fraenkel, which at another time would have probably attracted more attention, was eclipsed early in 1896 by the announcement of Baumann (the Freiburg chemist who has just passed away while in the renown of his greatest achievement), that he had found in the thyroid gland, not only of man but also of various animals, an amorphous body containing a large amount of iodin, and which possesses all the physiologic characteristics of the gland. Moreover, on removal of this substance the residue of the gland retained no activity whatever. This substance he named "thyroiodin."

Thyroiodin, according to Baumann, is a brownish colored, amorphous compound, which upon heating is decomposed with considerable swelling and with an odor of pyridin bases. It is almost insoluble in water; in alcohol it dissolves with difficulty. In dilute alkalies it is readily soluble and from such solutions is again precipitated by acids. Concentrated sodium hydroxid, upon heating, brings about gradual decomposition. It manifests no proteid reactions, although it is constantly found to contain phosphoric acid in organic combination, which is probably not part of the thyroiodin molecule, since it is present in as large proportion in impure as in pure thyroiodin. By analysis he ascertained that in the purest obtainable thyroiodin there was 9.3 per cent of iodin, which is probably below the true proportion, and he was able to obtain the iodin itself in crystalline form from this substance.

The methods used for its extraction depend upon the fact that it is an extremely stable body, resisting the action of boiling 10 per cent. sulphuric acid for three days, and being entirely unaffected by digestive ferments. To isolate the thyroiodin the finely chopped gland is placed in about four times its weight of 10 per cent. sulphuric acid in a flask connected with an inverted condenser, and boiled for about eight hours. On cooling the mixture it will be found that, except for the fat floating on the surface, all of the material but a brownish precipitate has gone into solution. This precipitate is the thyroiodin, although yet in an impure form. After skimming off the fat and filtering, the residue on the filter paper may be purified by a succession of extractions with boiling 85 per cent. alcohol. The filtrate also contains a little of the thyroiodin which can be obtained by nearly neutralizing with barium carbonate, filtering, and concentrating the filtrate, when most of the contained thyroiodin will be precipitated on cooling. Thyroiodin may also be obtained by acting upon the gland with an artificial gastric juice, keeping the mixture at 40 degrees C. for two days, when the thyroiodin will be left alone as a precipitate. It can then be purified as above.

The iodin was believed by Baumann to exist in combination with two proteids, the larger proportion being in combination with an albumin, the smaller with a globulin which is apparently identical with the thyreo-globulin of Bubnow and Notkin.

At the time Baumann made his announcement, Hutchinson, in England, was studying the colloid substance from a chemical standpoint, and had separated by gastric digestion a non-proteid substance which represented about 3 per cent., of the pure colloid. On the appearance of Baumann's report he investigated this substance further and found it to be thyroiodin, and moreover he was able to show that it was all contained in the colloid substance as it exists in the acini of the gland, thereby establishing that the colloid is the true secretion of the thyroid gland and contained its active constituents. He found that it contained all of the phosphorus of the colloid and most of the iodin, a small amount of the latter existing, as Baumann had believed, in some other form. As a result of his work Hutchinson concluded that the thyroid gland contained two proteids, one a nucleo-albumin which is present in small amounts, probably in the cells lining the acini; the other the colloid which contains 15.5 per cent. of nitrogen and 0.045 per cent. of phosphorus. The colloid is not allied to mucin, nor can nuclein bases or para-nuclein be obtained from it. It can be split up into two parts; a non-proteid and a proteid part, of which the former is the thyroiodin, while the latter contains a smaller amount of iodin and possesses less physiologic activity. The colloid is the only active constituent of the gland, and the extractives, which are quite abundant, have no specific action. Hutchinson believes the thyroiodin to consist of a globulin loosely united to a non-proteid body containing sulphur, phosphorus and iodin.

While Baumann was studying the chemic nature of the thyroiodin, Roos in the same laboratory subjected it to physiologic and therapeutic tests which showed it to be beyond doubt the active principle of the gland. Three or four one-milligram doses of thyroiodin showed a very decided action on goiter, which unquestionably could not have been the result of the one-tenth milligram of iodin contained therein acting simply as iodin, but must have been due to the specific organic iodin compound acting as a compound body. It also produced all the effects ascribed to the ordinary extracts or to the gland itself, such as the toxic effects of large doses, the specific action on myxedema, and the influence on metabolism in both man and the lower animals. Moreover, Roos believed that it exercised its power more quickly than do extracts of the gland or the fresh gland when given as such, ascribing this to the gradual splitting off of the thyroiodin during digestion and the transformation of part of it into inactive substances, in contrast to the immediate absorption of the free thyroiodin. In his experiments Roos not only proved the activity of the thyroiodin, but proved that any preparations from the gland, so made that it contained none of this substance, produced no effect on goiters that were readily influenced by pure thyroiodin. He also found that its activity was destroyed by boiling with strong alkalies, and was not affected by solution in weak alkalies in the cold, nor by the action of digestive fluids.

After having demonstrated the presence of thyroiodin as a constant occurrence in the thyroid gland of both man and the lower animals, Baumann began to determine the quantity normally present in the human gland. These investigations led to very interesting and suggestive results.

His first determinations were of glands obtained in Freiburg. from natives of that vicinity. In a series of twenty-six glands he found the average dry weight to be 8.20 grams, containing in each gram 0.33 mg. of iodin or in all 2.5 mg. of iodin to each gland. Since the iodin represents 10 per cent. of the weight of the thoroiodin, the average amount of thyroiodin was 25 mg. The amount in different glands varied, in some being little more than a trace, while in four the amount was over 10 mg. and they were not included in the list. These cases were:

1. Woman dying of tuberculosis whose gland weighed 9.3 grams and contained 35.3 mg. of iodin. 2. Woman dying from carcinoma of uterus, weight of gland 6.5 grams and contained 22.9 mg. of iodin. 3. Woman, heart failure, gland weighed 10.7 grams and contained 14.9 mg. of iodin. 4. Man, heart failure, weight of gland 12 grams, iodin content 10.8 mg.

Since Baumann has proved that administration of iodin and iodin-containing foods (fish, etc.) to dogs greatly increased the amount of iodin in their thyroid glands, the possibility of these high results being due to administration of iodin previous to the death of the individuals was suggested, and in the second of these cases this was true, the woman having had iodoform dressings applied for some weeks, but in the other cases there was no evidence of iodin administration.

As is well known. Freiburg is in a district where goiter is endemic, and Baumann considered that possibly the amount of iodin might be different in regions where this disease is not prevalent, especially since he had found that goitrous glands contain but little iodin in proportion to their weight. That this theory is well founded is shown by the results of the analysis of thirty glands obtained from Hamburg, where goiter is of comparative rarity. These glands averaged 4.6 grams in weight, each gram containing 0.83 mg. of iodin, the total amount being 3.83 mg. in each gland. This is about one-half more per gland than was obtained in the Freiburg glands, whereas the weight of each gland was about one-half that of the latter. Here also were excluded four cases in which were found over 10 mg. of iodin, in only one of which was there a history of administration of iodin preparation.

Eleven glands from Berlin, where goiter is not endemic, were analyzed. They were mostly obtained from people meeting sudden death from accident or suicide. The average weight was 7.4 grams, each gram containing 0.9 mg. of iodin, giving a total of 6.6 mg. of iodin to each gland. Here the weight of the gland was nearly as high as in those obtained from Freiburg, but the amount of iodin is triple that of the latter, and double that obtained in the Hamburg glands. But it is to be considered that these glands are from people in full strength and middle age who met sudden death, while the results seem to show that the amount diminishes in old age and wasting diseases; however they contain three times as much iodin as do the glands from Freiburg suicides. In this series two cases were excluded; one a goitrous gland weighing 28.2 grams and containing 14.2 mg. of iodin; the other contained 22.7 mg. of iodin to only 5.4 grams of gland substance, an average to each gram of 4.2 mg.

The thyroid glands of children show, even more clearly, the variations in the iodin content in these three localities. In twelve Freiburg children under one and one-half years of age in only three glands was a trace of iodin found, amounting from 0.07 mg. to 0.18 mg., while the average weight of the glands was 1.5 grams.

The average weight of the glands from six Hamburg children was but 0.36 gram, yet five of them contained iodin, the average amount being 0.26 mg. per gland, while in the sixth a trace of iodin could be detected.

The glands of the six Berlin children averaged in weight 0.4 grams each, and five of them contained iodin, averaging 0.4 mg. to each gland.

So it follows that in Freiburg where goiter is endemic the weight of the gland is highest and the amount of iodin the lowest, in comparison with Berlin and Hamburg where it is not endemic. Therefore it is probable that there is some relation between the prevalence of goiter and the amount of iodin which is ingested by the inhabitants of the various localities, apparently an inverse ratio. This iodin may be contained in the drinking water, and in support of this idea is the popular belief that goiter depends somehow on the water supply, which has led to the theory maintained by Klebs and others that it is due to flagellata, bacteria, or other parasites residing in the water. Moreover, chemic analysis seems to indicate that the drinking water in goitrous districts really does contain less iodin than does that in other localities. The food may also be the source of the iodin, for many plants contain this element in their ashes, notably the beet root, and the same can probably be said of fish. It is a well known fact that thyroidectomized animals live much longer when fed upon vegetables than when given a pure flesh diet and the iodin content of the gland diminishes under the last regimen, either because a flesh diet prevents an accumulation of the thyroiodin, or else by its influence on metabolism it requires an increased expenditure. Again much of the iodin may be obtained from the the air, since the sea air as well as sea water contains this substance, and goiter occurs much more in the inland districts, especially when shut off from the sea winds by mountain ranges, than on the coast, as is well shown by the maps illustrating the relative distribution of goiter.

Since Baumann's work throws so much light on the relation of thyroiodin and goiter to locality, it seemed to the writer that it would be extremely interesting to determine the amount of iodin contained in the glands of residents of Chicago and of other parts of this country. As is well known, goiter can not be said to be truly endemic in any part of the United States, although Osler believes that it is endemic in the limestone region of eastern Ontario, where 288 cases were observed in a hospital population of 600, and the condition was noticeable even in the lower animals of the vicinity. Many writers, early in this century, state that goiter is endemic in the valleys of Vermont and other regions, but while this may have been true at that time it is not so now. The other thyroid diseases, *i.e.*, myxedema and cretinism, are also very uncommon, but exophthalmic goiter would seem to be slightly more prevalent. That this relative immunity from goiter in all parts of a country which contains almost every possible condition of climate, soil, water and food supply, elevation and distance from the seacoast, is due to a universally favorable condition as regards iodin supply, seems scarcely possible. It is much more likely that it is due to the migratory nature of our people and the intermarriage of people from different districts, which prevents the changes produced by long continued lack of iodin in sufficient quantities from adding up from year to year and from generation to generation, resulting in a goitrous diathesis. Possibly when the country is more thickly inhabited and its people have settled down this disease will begin to appear in certain regions, as is now observed in the older countries of Europe.

In order to find out what information could be obtained on these points by chemic analyses, it was decided to determine the iodin content of the thyroid glands of people who had spent at least a considerable part of their lives in Chicago or its immediate vicinity, and to compare them with the results obtained by analysis of the glands of residents of the different parts of the country, as Baumann had done.

For this purpose there were available the glands removed in the autopsies in the Cook County Hospital, which were especially desirable since history sheets giving information as to previous administration of iodin as well as the history of the subjects were usually obtainable. Through the courtesy of Professor Hektoen, Dr. Edwards and Dr. LeCount a large number were secured. Through the kindness of the following gentlemen glands from their respective cities have either been secured or promised: Prof. W. H. Welch of Baltimore, Prof. T. Mitchell Prudden of New York, Prof. W. T. Councilman of Boston, Professor Adami of Montreal, Dr. H. W. Cattell of Philadelphia, Dr. J. T. Eskridge of Denver, and Professor Smith of Galveston.

The glands to be examined were kept in alcohol until used, which, on account of the comparative insolubility of thyroiodin in cold alcohol, together with the immediate coagulation of the tissues, can be safely done. Analysis of the alcohol in which twenty glands had been kept for two months, showed that the loss by this means was at the most not over one-thirtieth of the total amount of the iodin contained in the glands. After this dehydration by the alcohol they can be quickly dried in the drying oven, if they first be cut up into small pieces. They are then weighed, and for purposes of analysis are ground into a fine powder in an ordinary drug-mill, an apparatus that can be easily and completely cleaned being necessary so that one gland does not become mixed with portions of the gland that was previously ground.

After considering the methods available for the estimation of iodin it was found best to adopt the colorimetric method as used by Baumann, with certain slight modifications which the writer found necessary to obtain the most accurate results. The analysis is conducted as follows:

One gram of the dried and powdered gland is placed in a covered silver crucible of 50 c.c. capacity. To this is added about 2 or 3 grams of powdered sodium hydroxid and enough water to make a thick paste. The mixture is heated cautiously, with the cover of the crucible pushed to one side to leave a crack for the escape of steam. Great care is necessary at this stage of the process, to prevent the mixture boiling too high, a catastrophe sometimes very difficult to avoid. When all the water is driven off, the cover is placed completely on, and with the least possible amount of heat the residue is carbonized. When combustible gases have ceased to escape the flame is removed and the crucible and its contents are allowed to cool slightly. Then the least possible amount of finely powdered potassium nitrate necessary to produce complete oxidation of the carbon, generally about 1 gram, is added, and after replacing the cover this is accomplished with as little heat as possible. By heating with the sodium hydroxid, the thyroiodin is decomposed and sodium iodid formed, the excess of the alkali preventing the formation of insoluble silver iodid, and also of volatile compounds of iodin.

After the residue has been cooled it is dissolved and the solution is filtered into an Ehrlenmeyer flask. This step of the process may be hastened by the use of the filter pump. To the solution is added 20 per cent. sulphuric acid until it is acidified, much carbon dioxid being given off, owing to the formation of sodium carbonate, during the fusion. On account of the presence of nitrites in the solution, as soon as the fluid becomes acid the iodin is liberated, generally in sufficient quantity to give 50 c.c of fluid about the color of normal urine. To the fluid is now added 10 c.c. of chloroform and the mixture thoroughly shaken, the chloroform settling out with the characteristic pinkish color always produced by small quantities of free iodin. The contents of the flask are now poured into one of a pair of matched cylinders, which should not be over one inch in diameter nor less than six inches in height. Into the other cylinder is poured 10 c.c. of chloroform, 15 c.c. of a saturated solution of sodium sulphate, 15 c.c. of water, and a few drops each of a 5 per cent., solution of sodium nitrite and of 20 per cent., sulphuric acid. The sodium sulphate prevents cloudiness of the chloroform after shaking, while the sodium nitrite liberates iodin from the standard solution which is to be added. The standard solutions used are two. The first contains 1 mg. of pure potassium iodid in each cubic centimeter, the second is but one-tenth as strong.

To the second cylinder is now added the standard solution from a burette, until, after shaking, the chloroform is colored to the same degree of intensity as that in the first cylinder. The amount of iodin in the specimen analyzed is then readily determined by a simple calculation based on the fact that each cubic centimeter of the stronger standard solution contains in combination 0.76 [illegible] By practice diff.

ences representing one-tenth of a milligram of potassium iodid can be readily detected, best when 10 c.c. of chloroform is colored by between 1 and 2 mg. of iodin. If the unknown solution contains more iodin than this the chloroform in each cylinder can be increased to 15 or 20 c.c.

This method commends itself both for rapidity and ease of application, which are essential features in making a large number of determinations as in this case. It is also very delicate, amounts between two and three one-hundredths mg. of iodin being detected by reducing the amount of chloroform to a few drops. On the other hand it is not extremely accurate, a certain amount of loss being inevitable; but since the loss is small and the results are comparative, this is not of extreme importance.

TRANSLATED FOR THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION BY CARL H. VON KLEIN, A.M., M.D.

XV. DISEASES OF THE BONES, JOINTS AND MUSCLES.

(Continued from page 854.)

In regard to *position*, J. L. Petit taught that patients with fractures of the lower extremities must be put on mattresses (sometimes divided) and not on feather beds, and in the use of apparatus, boards should be pushed under the mattresses to prevent them from sliding; and the sound foot should be able to support itself on a block. In femur fractures he had holes made in the mattress to avoid a decubitus and that the bedpan might be pushed underneath. How often even yet are these teachings transgressed in private practice, although they have been continually preached for 170 years by the best surgeons! The bandaged fracture was almost always laid in extension. Indeed, independently of Fabr. von Aquapendente, Bromfield, Kirkland and Sharp, even in the forties and fifties, had flexed the upper thigh and laid the patient on his side; but Pott deserves the credit of having scientifically estatablished the method of the bent position also for after-treatment, and of having introduced it into general practice. When Wilmer, on the contrary, insists that Galen had already recommended the flexed position, Richter justly remarks that it is as worthy to bring to light-again an old forgotten truth as to discover an entirely new one. In femur fractures Pott had the whole body turned to the injured side, laid the upper thigh with the outer surface upon a broad, hollow and cushioned splint, besides, a short splint on the inner side of the thigh and fastened with the eighteen-headed bandage: the knee was somewhat bent and the foot placed a little higher than the thigh. He followed this principle of bending in all fractures, except that of the patella and of the olecranon. Pott's lateral position made a great sensation; they contended for and against it. It established itself in England quite generally, but was soon modified. Aitken had the broken thigh flexed, to be sure, but placed the patient on his back because he could not endure the lateral position for weeks at a time. On the other hand, Wilmer observed that in the dorsal position the fragments of the femur so united that the point of the foot is turned outward. In Germany, Richter adopted Pott's position, but with other surgeons preferred that of Aitken for all cases in which the injury was on the dorsal side of the thigh. He designated as a further exception to Pott's rule, the case in which the femur was broken in two places, in the middle and above the knee; then the limb must be extended, because a displacement always occurs in a bent position. The French, especially Desault, Bichat and Boyer would hear nothing of the lateral position; Dupuytren first turned his attention to it. On the first day of the injury Richter, who laid the limb on a sack filled with fine chaff, confidently gave opium; on the following six or eight days mild purgatives, and if severe inflammation was feared he bled the patient.

In *complicated fractures* a middle ground appeared between conservative treatment and amputation. Pott taught always to amputate when the bone was shattered in little pieces, the joint crushed, or the laceration of the soft parts so extreme that mortification must necessarily follow. His arguments are in part very similar to those put forward today in the question as to the treatment of gunshot wounds of the knee. He admits that conservative treatment does not always miscarry in these complications, but experience teaches that as a rule such a limb can not be preserved and the patient perishes, and the danger of amputation is never so great as that which follows such an injury. He amputated either at once, which was best, or later, when the bones did not knit, with strength exhausted by excessive suppuration, and finally when mortification threatened. If this were already present one should not amputate, because death is thus hastened, but he should assist nature to resist mortification. Allen Kirkland, who entirely approved of the other doctrines of his master as to position, splints, etc. opposed Pott's principles as to amputation. (Compare gunshot fractures in Chapter 20.) He valued them most highly in the hospitals, but not for private practice, because the country surgeons reported excellent results in complicated fractures; out of twenty cases they scarcely amputated one, and by conservative treatment they lost at most one in ten. The hospital conditions were of course of a different sort and justified amputation; the air was bad and in the hospital diet little regard could be paid to the manner of life of the individual patients. On the other hand the patient in the country enjoyed all the advantages of fresh air and could be invigorated by beer, wine brandy, etc., so that a cure without amputation was almost always reported. Not that alone, J. Hunter knew that it is often possible to treat a complicated fracture as a simple one. Likewise did Kirkland, who found more honor in preserving a limb than in cutting it off. Gooch, after forty years experience, asserted that mortification should never force a surgeon to a too hasty amputation, and Wilmer discarded the primary operation decisively. Richter declared himself in favor of it on account of the better prognosis, although he advised that conservative treatment be employed whenever possible. B. Bell, who regarded the principal danger as allowing the admission of outer air to the fracture, recommended secondary amputation, especially in case of after-hemorrhages where on account of inflamed swelling and coagulation of the blood a direct ligature was impossible, and also in case exhaustion ensued; for as soon as the seat of suppuration had been removed by amputation the patient improved in a striking manner (A. Monro and Bromfield). With the secondary amputation he had often obtained a fortunate result and it had never resulted fatally, while he had seen many die from primary amputation. In general it appeared to him as necessary in private practice, but much less often than in the great hospitals and in the field.

In the interests of conservative treatment, Pott as well as Richter condemned the too hasty sawing off of the bones which protruded through the skin, since the flexed position and the enlargement of the wound often sufficed for the setting of the bones, and they sought to bring into favor splints, and the eighteen-headed bandage, which had been hitherto considered injurious. When inflammation set in, Pott applied a poultice, with which, however, in England great abuse was practiced, by applying it to simple, fresh fractures; and instead of pressing out the pus with compresses he encouraged the knife-fearing surgeons to make larger and counter openings. He laid soft dry lint in the wounds, but so loosely that it neither irritated nor checked the excretion of pus; in case of violent inflammation he resorted to bleeding, and in copious suppuration he gave strong nourishment and quinin. These methods were approved by Kirkland, only he warned against repeateded bleeding, bandaged with digestive balsam, and in order to protect the bandages from pus covered the compresses with oiled silk. Wilmer also condemned much bleeding and poulticing, and in place of the latter he early applied cooling and resolvent agents in order to avoid amputation, and also gave opium in large doses. When the Lyceum Med. in London called for a prize essay on the best treatment of complicated fractures, Weldon (1794) added to the familiar indications for amputation, those pertaining to a fracture in the joint. He bound up the injured arteries but performed an amputation, even though the injury were slight, if the bleeding vessel could not be exposed, if the hemorrhage could not be stopped, or if a ligature was impossible by reason of excessive swelling. In conservative treatment he advised the attempt to make a prima intentio when possible.

In case *no union* of the fracture resulted, White employed various remedies; one was rubbing the ends of the bones against each other, by which he healed a femur fracture in six months, after which he had the patient get up and go about on crutches. Likewise he first recommended the resection of a broken bone (1760), which he performed with success; the fracture was laid bare and both fragments sawed off, after which they were treated with caustic. Hunter had the broken bones scraped. In case of fractures healed crooked, so long as the callus was not very firm, resort was had to continuous extension: yet the rebreaking of the malformed bones, already recommended by Celsus, was practiced. In case of an angularly healed femur fracture of a child sixteen weeks old, the Dutchman Tenhaaff, sought to soften the hard callus first by poultices and quicksilver salve and then broke the bone in two, whereupon the fracture knit anew (1775.) Richter feared that in such a case the bone could easily be broken in another place.

Of particular fractures let us notice only a few which aroused special interest at that time. In no fracture were so many appliances resorted to, but with so little success, as in that of the *clavicle.* The patient was fastened to a great cross of wood or iron (Heister), indeed a new "comet" was devised for that purpose (Baas). The first step in advance was the bandage submitted by Brasdor to the Académie de chirurgie in the year 1774. In order to draw the shoulders back and hold them continuously in this position he applied a half bodice which covered the back, and, with two leather halves, drew back the shoulders. Evers improved this bandage and introduced it into Germany. Flajani, on the other hand (1785), left the patient without any bandage, and only had him lie continually on his back with the sound shoulder supported, the injured one over a hollow. Then Desault came forward with his new bandage (1787), which first gained for him a reputation in surgery. In the knowledge that the outer fragment is drawn downward by the weight of the shoulder, and forward and inward by muscles, hence it is only necessary to support the shoulder and draw the fragment outward and backward, he devised the well known wedge-shaped cushion which, placed in the armpit, brings the arm as if over a fulcrum, near the trunk below but separated from it above. In order to prevent the sinking of the fragment, B. Bell (1788), who ignored both the French inventions, was satisfied with raising the arm by means of a napkin. Finally Brünninghausen appeared with his brace (1790), which, as he said, was so easily adjusted that almost any peasant could properly cure a fracture without the help of a surgeon. He appreciated Brasdor's bandage, but disapproved Desault's method which Richter favored, and he inveighed against B. Bell. Certain fractures of the *ribs* and sternum were treated with surgical frivolity. If the broken rib pressed inward, the breast cavity was opened, and the fragment pushed outward with the finger, pincers or a spatula (B. Bell)! On the other hand, they trepanned every fracture of the *sternum* (la Martinière), because, on account of laceration and inflammation of the underlying parts, it offered conditions entirely analogous to cranial fracture. Later, trepanation was limited to cases in which it was impossible to raise the depressed fragment (B. Bell, Böttcher), or to extravasation and suppuration in the mediastinum (J. L. Petit, Richter); it was finally discarded entirely (Ch. Bell).

Desault treated fractures of the *upper arm* by adjusting a circular bandage around the arm, a forward, outer and inner splint, and a wedge-shaped cushion in the armpit, and having the forearm carried in a sling. Desault also often observed fractures of the *lower end of the forearm, with condyles,* which are not mentioned by the ancients, nor by Petit, Duverney and Bell. He introduced into general practice (1791) the treatment with the extended arm in fractures of the *olecranon,* although Duverney first suggested full extension, and the Englishman Haighton had even earlier (1785) reported a cure in this position. Desault pressed upon the fragment by envelopment and adjusted to the anterior side of the arm a splint slightly bent at the joint, to prevent flexion, but avoided too great extension. In fractures of the *forearm* they sought for means to put the four fragments against each other correctly, while the teaching of Hieronymus Brunswik, to lay the arm in perfect supination so that the patient always looks straight above him, was for a long time forgotten. They laid rolled bandages between the bones (Pouteau), cylinders an inch and a half long above and below the fracture (Richter), and even long narrow compresses from the wrist to the elbow (Aitken); the hand was kept in the position in which the patient fo[illegible] the least pain, *i.e.*, half-way between pronation and supination (Richter, Bell, Desault). Desault applied small compresses to both sides, and adjusted three splints and a circular bandage from below upward.

As mentioned before, the fracture of the *upper thigh* principally brought to a close the contention over Pott's lateral position. Desault became its strongest opponent after he had twice tried it and, in spite of the most careful treatment, a considerable shortening had followed. After that he discarded it because of extension and contra-extension, of the impossibility of accurately comparing the injured thigh with the sound one, the hardship of the position after a long time, the painful pressure on the trochanter, the difficulty of defecation and the lack of a sufficient fixation of the bone. Instead of the lateral position, Desault, with the best results, made use of the continuous extension method decried by most surgeons, and then, principally with him, the perfection of the extension bandage begins. Through this method, by means of a bandage laid over the joints and a strap around the chest and shoulders, etc., the great danger of a femur fracture at the knee joint was lessened. For the rest, there was no lack of newly invented apparatus (Gooch, Theden, Aitken and others). They recognized the great difficulties of diagnosis between fracture and luxation of the upper part of the thigh, which confusion A. Paré has been honest enough to confess. Our countryman, Schneider, had devised (1768) an extension apparatus for this fracture; he passed above the knee two cords which could be drawn tightly to the bedstead by screws, while for contra-extension, two cords which fastened to a leather girdle secured around the hips and passed through the upper part of the bedstead; an outer splint prevented flexion. Desault effected extension by means of a long wooden splint attached to the outer side. It was actual abuse when Sabatier applied only a straw splint and at first did not hesitate to repeat the setting several times a day until after two or three weeks the convulsive muscle contraction ceased. Brünninghausen wrote a peculiar monograph on this fracture; he bound the injured thigh fast to the sound one and adjusted an outer splint to the upper thigh. His teachers, Richter and Siebold, and also Theden, recommended this method, which, however, had been accurately described several years before by the Dutchman, Van Gesscher ("Richter's Chir. Bibl.," XIII, 322).

The fracture of the *patella* aroused great interest by the question as to whether it could be cured at all. Hitherto denied by the Académie de Chirurgie, Camper, Sheldon, David and Böttcher pointed out the true callus, while Callisen in forty sections did not once observe the slightest trace of such a thing, but only a viscous or cartilaginous intersubstance. Aitken admitted cures in three ways, by true callus, tendinous or membranous matter. And then it was argued, pro and contra, whether a setting should be made immediately (Mohrenheim) or only after reduction of the swelling, since if one has no control over the vessels, he can not often bring about an accurate adjustment (Pott, Bromfield, Acrel). Many attached no value whatever to bandaging, and recommended only rest and antiphlogistics (Warner). Many appliances and bandages were suggested for the accurate adjustment of the fragments in an extended position (Mohrenheim, Theden, Evers and others). Richter reported cures by a simple envelopment from the point of the foot to the abdomen, with the adjustment of a long narrow compress over the upper fragment; and Desault considered a bandage applied in extension as sufficient. At the end of the second or third week, passive movements were begun (B. Bell, Bromfield), to guard against a persistent stiffness. Posch (1774) facilitated the treatment of fractures of the *lower part of the leg* by his so-called Fussbett (foot-bed) in which the broken limb hung in suspension by straps, and could be extended by means of cords at the knee and foot. This apparatus received much applause in Germany. An appliance of Pieropanos of Vicenza came into use in Italy (1780); it effected extension by means of long screws on a brass plate which bore a shoe. This appliance was introduced into all the hospitals of Venice and of the kingdom of Naples; indeed, the High Council of Venice had gold and silver medals struck in honor of the inventor.

In *caries* Alexander Monro, senior, first called attention to the analogous process of the formation of abscesses in the soft parts. Richter distinguished between dry (Petit's designation) and moist caries, divided the latter, according to the nature of the soft parts, into hidden and open, and admitted moreover a malignant caries, which either as spina ventosa has its seat in the spongy bones, or as exostosis maligna is a completely ulcerated abscess of the bone. For the cure of caries only a separation of dead from living bone was necessary, which they endeavored to accomplish by means of instruments, or which was left to nature by exfoliation. To accelerate the latter process, they moistened the part with brandy or liq. bellostii, used the hot iron, bored into the bone and injected those liquids, or they removed the diseased part by means of a scraper, chisel or trepan. The recently much discussed *évidement des os*, according to Sédillot, is nothing new, since Heister recommended the scraping out of the foul matter with scraper and chisel until one should come to healthy bone substance. Amputation, recommended by J. L. Petit in persistent caries, was only allowed when the caries had completely laid hold of a large bone shaft or a joint, and the soft parts were at the same time corroded. In caries following gunshot fractures, Bilguer had been able to avoid amputation and, as we have seen in the last chapter, restricted his treatment to the so-called *évidement*, scraping out and a complete extirpation of the separate wrist and ankle bones, a treatment which is customary even today. If the soft parts had suffered only a little, resection was recommended. Richter also favored this, since nature replaces the lost piece, and the limb not only retains its former length, but also the movement of the joint.

Pott discovered caries of the vertebral column *malum Pottii*, and described it in a masterly manner Hitherto the paralysis of the lower extremities, arising from this disease, had been regarded as the result of an unnatural curvature of the spine, so that no one considered any treatment but to straighten the spinal column by means of instruments. His attention was aroused when he observed the paralysis leave a child and a cure take place after opening an abscess on the spine supposed to be fortuitous. Although he designated the disease as paralysis (palsy of the lower limbs), yet he did not suppose that it was the result of a lump on the neck, back or hip, but that both depended on an as yet unknown cause. Then by dissection he found, in the extreme stage of the disease, the vertebral matter entirely carious; in a disease of short duration it was only swollen, and the ligaments thick and flaccid. Chance defined his treatment, which has become classic. In Worcester, Dr. Cameron related to Pott that an observation of Hippocrates, in which a paralysis of the legs is regarded as caused by an abscess of the spine, had induced him to make an artificial ulcer near the hump in a similar case whereupon a complete cure followed. A surgeon of that place, Jeffreys, confirmed this and asserted that he had had similar results. This induced Pott to apply to both sides of the hump a seton or an issue made with a corrosive, and often kept it flowing several months until the patient was able to walk about. He saw many cases of paralysis cured under this treatment. Sometimes the humps disappeared entirely and the constitution improved, and he recommended applying the issue as early as possible, because in fully developed caries the disease was incurable. In the same year as we have mentioned before, David in Rouen made his observations public and remarked that caries of the vertebral column is not incurable and that the process of cure is the work of nature, time and rest. When Bouvier first snatched this work from oblivion (1858) he established for his modest countryman the honor of priority and reviled Pott as a blatant braggart in every way. Michaelis was an eye-witness of almost twenty successful cases in Bartholomew's Hospital, and he immediately reported them in Germany. It is astonishing that Richter found no word of recognition for the great discovery of his highly esteemed teacher, and even said that this disease was not frequent with us. This was known scarcely four years when the treatment began to deteriorate. It had already come to pass that Pouteau replaced the issues with moxa, which Desault also preferred; but Sheldrake taught anew the dangerous doctrine that an apparatus should be applied to the patient to correct the curvature of the spine. Although B. Bell was quickly at hand to banish all apparatus as in the highest degree injurious, yet throughout many decades that doctrine wrought disaster. Bell had the patients sleep on horsehair mattresses with boards underneath, never on feather beds, in order that the body might lie as nearly horizontal as possible, and he had them discontinue all tonics and cold baths. In this way one could check the disease in the beginning, for as soon as the bones were attacked a perfect cure could not be accomplished, and whenever the issues were successful the disease had had its seat only in the ligaments, not in the bones themselves. Ford also discarded the apparatus because they separated the vertebral substance and prevented ankylosis. He found that the results of the artificial ulcers were better the higher up the curvature was. According to Loder, who attached great importance to the early recognition of the disease, if one suspected the beginning of caries, the only help lay in an incision reaching to the bone, which should be transformed into an issue; superficial ulcer, even moxa, availed nothing.

Necrosis was described by Ruysch and Jacob von Meekren; but the older surgeons regarded it as only a special form of caries, and until recently the two diseases were not always sharply defined. Troja produced necrosis artificially in animals, and found that one could accelerate the formation of a new bone in no way more surely and rapidly than by completely destroying the marrow in the old. Upon this he established trepanation of bone cavities. Multifarious experiments on animals were made in order to clear up the dark question of the regeneration of bones: this was especially so in Germany on the part of Blumenbach and Roeler. The latter, a pupil of Richter, sawed off the caput femoris with the trochanter major of dogs (1786), and found the result important for the reconstruction question in that the animal could run about again after four weeks. In postmortem no new head was found, to be sure, but on the sawed ends there were many rounded protuberances of bone, from which new tendinous ligaments proceeded to the edge of the hip socket where they had grown fast. David produced the first scientific pathologic work on the disease to which Louis gave the name necrosis ("Obs. sur une maladie d'os connue sous le nom de necrose," Rouen, 1782). In it he disputed with a colleague who considered the experiments of Troja and others as to the formation of new bone as erroneous, and the operation of taking the old bone out of the new cylinder as useless. David regarded necrosis as a disease of the periosteum. If the periosteum becomes bruised inflammation arises, from which pus exudes between it and the bone and the two are separated. Then the exposed bone mortifies, the periosteum swells from the newly supplied fluids, becomes thicker, at last ossifies and forms a new shaft around the dead bone. The many fistulous openings in the new cylinder arise from the pus which at first corrodes the periosteum and forces its way outward; through them the sequestrum can be seen and drawn out. Formerly they had bored great holes into the case of the tibia with the trepan and cauterized the bone (J. v. Meekren, J. L. Petit). David first performed necrotomy by means of a hammer and chisel and drew the sequestrum out. For example he extracted ends from the humerus and tibia, a piece seven inches long from the femur, and advised afterward that the hot iron be applied to the entire inner cavity of the bone. With this operation, which he recommended early, he avoided the hitherto frequently employed amputation. In England Walker, who likewise considered amputation unnecessary, had performed this operation successfully for many years; once he trepanned the humerus in almost its entire length so that it lay open before him, and removed the sequestrum. Bousselin called attention (1785) to the fact that sometimes after months and years nature is able to loosen and discard the sequestrum, and the fistulas heal of themselves; but before the operation one must convince himself of the movableness of the sequestrum. Desault once opened the entire tibia with a chisel, and extracted a sequestrum which extended nearly the whole length of the bone; the fissure was filled with rolls of lint, and after fifteen months the patient was able to walk. Weidmann produced the first detailed work in Germany ("de necrosi ossium," 1793). He distinguished sharply between caries and necrosis, as between abscesses and inflammation, and included under necrosis mortification and disjunction of the bone, without considering, with David, a replacement by new bone substance was necessary. But that nature could replace the disjoined pieces of bone, Weidmann and Percy observed in the lower jaw, Moreau in the clavicle, Chopart in the shoulder-blade, and Warner after the extraction of an entire tibia which was completely regenerated. For the formation of bone it is first of all necessary that the periosteum, as the chief source of nourishment, be preserved. Hence Weidmann, who introduced the name cloaca, advised "in all operations in which one endeavors to separate and extract the pieces of dead bone, to spare the periosteum as much as possible." (C. C. v. Siebold separated the periosteum with a spatula before he applied the trepan to the bones.) He has the credit of having introduced sequestrotomy into general practice, although it struggled long for admittance; even Dieffenbach regarded the operation as dangerous and refused to use the chisel.

J. L. Petit offered the first observations as to the purulent *osteomyelitis* appearing after injuries. The one concerned a simple contusion, the other a gunshot wound in the tibia; in both cases death ensued under serious circumstances, and along with liver abscesses a suppuration of the marrow cylinder was found. The history of *abscesses in the bone* also goes back to J. L. Petit; he saw such an abscess on the tibia in syphilis, and first cured it when he cut out a great piece of the bone by application of four trepanations (1723). *Exostoses*, if they were not based on dyscrasia, were in special maladies removed with the chisel or trepan; on the other hand if they surrounded the bone the entire piece was sawed out, an operation which Richter in general rejected as too dangerous. J. L. Petit had already operated for cranial exostosis.

In the teaching as to *luxations*, until the eighteenth century brute force alone prevailed; the invention of new apparatus was for the most part the main object. Many of them were better adapted to tear out a limb than to set it, and most of them so constructed that one was not able to control them. Here, too, we owe the greatest progress to foreigners. J. L. Petit recalled the method of the ancients to bring a joint back into place in the same way in which it had been wrenched from the socket by the capsular opening, or as White expressed it, to set the limb again in the same position and direction in which it was dislocated. Petit had extension and contra-extension applied equally, but brought them to bear gradually on the dislocated limb itself, and the binding cord approached the condyles, which were protected by bandages. It was a great merit of Pott that he condemned the forcible tractions by apparatus, and esteemed the skill of surgeons above them. Especially through him the question as to the retention of the ligaments of the joint in luxations, was raised. He regarded them as very extensible so that they could bear a great strain, and therefore were seldom lacerated. However, the setting of a fresh luxation does not prevent laceration, for within twenty years in his great hospital he had never seen a luxation of the humerus which could not in time be adjusted, in which, to be sure, a laceration of the ligaments of the joint had sometimes taken place. On the other hand, B. Bell and Kirkland brought forward the fact that the capsule might remain uninjured in incomplete luxations, but not so in complete luxations, even sometimes being torn away from the bone. The difficulty in setting dislocations of long standing, Bell recognized principally in the fact that fat, muscles and cellular tissue crowded into the socket and prevented the bone from resuming its former position. In setting Pott had the force applied to the dislocated bone itself, and gradually increased, and he emphasized as a most important general principle, that all the muscles should be relaxed as far as possible by a proper position. With this object bleedings were made (Flajani, Loder), and purgatives (Yonge) and tartar emetic enough to cause nausea (Chessner 1757) recommended. After setting it they allowed the limb to lie unmoved for a few weeks that the capsule might reunite with the neck of the bone; if the limb was moved too soon the union was imperfect and the joint weak, and a slight cause might dislocate it again. In case of severe contusion inflammation and swelling of the soft parts, setting was postponed until these conditions were moderated by rest, a somewhat bent position, and leeches (Pott). When in a slight injury the relaxation of the ligaments of the joint had the greatest share in bringing about the luxation, cold baths and electricity were recommended (B. Bell). A large part of the hitherto surviving apparatus was discarded. For that purpose in Germany there came into use the crane of the Saxon regimental surgeon Mennel, who added to the pulley used by Schneider, a screw arrangement and crank (*Loder's Journ. f. Chir., iii*); this is almost the only appliance of which later times still make use. The danger and uselessness of setting old luxations were well known. When David set a luxation of the humerus several months old, inflammation and death followed the great violence employed. His specimens of shoulder joints, as well as Loder's of hip-joints, show examples of new and completely formed joint sockets in case of luxations of long standing. In case of complications with fractures, setting of the luxation was recommended to be first undertaken. On the other hand if the fracture was close to the dislocated joint Bötcher had the bone set first and the dislocation was not corrected until after the healing of the fracture, but on the extension of the fracture he sometimes observed that the ball of the joint immediately re-entered the socket. When the head had protruded through the skin Gooch advised that it be sawed off, in support of which Kirkland supplied some favorable observations showing that it preserved the use of the limb completely and intact.

Today physicians warn against lifting a child by the head "in order to show him the geese of Bremen," because death might result suddenly from *dislocation of the vertebræ* of the neck; 170 years ago that nonsensical custom, called "showing children their grandfathers," was very popular among the common people and was severely criticized by J. L. Petit on the above ground. He also showed that dislocation of the first cervical vertebra was the cause of death in hanging. This dislocation was known to have been successfully set in a few cases; the Englishman Harrup accomplished it by extension accompanied by audible crackling; Ehrlich also undertook it in life and death cases, and Desault made the reduction in the case of a child, with the remark that life depended on it. As an avidence that this dislocation does not always result fatally, Callisen, in making a postmortem found, by chance, an ankylosis of the third and fourth cervical vertebræ which had been wedged together. Sömmering (1793) wrote on luxations and fractures of the *dorsal vertebræ* and showed that the joint ligaments often resisted external violence more strongly than the bones, that one of the vertebræ could be dislocated in relation to its entire environment without causing sudden death, and that generally such an injury could be repaired. For a long time the possibility of this dislocation had been generally doubted (Duverney), or at least it had been thought hardly possible without a simultaneous fracture and immediate death, because it was always accompanied with laceration of the spinal marrow (B. Bell). Enaux (1784) observed the very rarely occurring dislocation of the *pelvic bones* in which the left os pubis stood two fingers' breadth higher than the right one; after a brief antiphlogistic treatment the patient walked about on crutches, whereupon the weight of the bone gradually effected the reduction and recovery ensued. J. L. Petit set luxation of the *coccyx* by inserting the finger into the anus.

In case of luxation of the *lower jaw* Petit recommended the old practice of placing the two thumbs upon the teeth farthest back and pressing downward and then backward; it was also advised that before pressing the jaw down it be first drawn somewhat forward in order to make it mobile, and that the thumbs be protected by thimbles (B. Bell). In spite of Petit's opposition, Heister advised a severe blow upon the sound side of the face, as an approved method. Ravaton had observed that in case of an imperfect setting of a one-sided luxation, chewing and talking might later be made difficult and even impossible. Zach. Vogel made the rare observation of a luxation in a backward direction ("Merkwurd. Krankengesch. 1. Samml," 1756, S. 150), concerning the possibility of which Petit and Monro had doubts. Loder would not deny this possibility, especially in imperfect formations, because in one of his specimens the joint-process was considerably lower and smaller on one side than on the other, thereby making possible such a displacement. Our time considered the backward luxation, without a simultaneous fracture of the anterior wall of the external passage of the ear, as impossible, until Croker King saw the condyle dislocated in a backward and upward direction, in consequence of a fall, without any fracture of the ear passage (1855; S. Weber in "Pitha-Billroth's Handbuch"). Aurran of Rouen (1771) first described luxation of the *sternum.*

J. L. Petit recognized forward, backward and under luxations of the *upper arm,* and described nine methods of reduction, among them especially that in a horizontal direction, which soon found favor (Heister among others). Charles White suggested extension upward, after the setting with the heel, a method which is usually ascribed to Astley Cooper, had often disappointed him, and he reported very many successes by the former method, especially in old cases. To be sure, he opposed Pott's rule of bending the forearm, but his idea was to use the arm as a lever which can exercise the greater force the longer it is. This method of vertical extension was first established scientifically by Mothe in Lyons. Desault recommended direct reposition, already known to Avicenna, by which the reduction was accomplished only by immediate pressure of the fingers upon the ball of the joint. Richter attached great importance to frequently changing the direction of the extension, applying a moderate force and in case the ball was dislocated forward or backward, he advised always drawing it a little downward before forcing it into the socket, in order to bring it back again in the same direction in which it was thrown out. In very energetic experiments in extension, Desault maintained that he had seen the development of an emphysema as large as a man's head, within a few minutes, and had at first thought it an aneurysm arising from the laceration of the art. axillaris. The setting of a luxation of the *elbow* in the backward direction required chiefly the bending the forearm during the extension (B. Bell). J. L. Petit admitted the possibility of a luxation in a backward direction; he also cured a case in which the lower end of the humerus had broken through the skin. He regarded the dislocation of the *wrist* as one of the most dangerous, because the reduction was quite difficult and the after-treatment long continued, while pains and an inequality in the joint remain, which cause many to believe that the setting was badly done or that a fracture had occurred. Soon doubts as to the frequency of this luxation were expressed (Pouteau and Desault), until Dupuytren denied it entirely and declared it to be a radial fracture. Desault first described a luxation de l'extrémité inférieure du radius, which Loder also afterward observed. The difficulty of setting a dislocated thumb was recognized by J. L. Petit and by Richter, who once worried himself an hour and a half over such a case. For this purpose the tendons and ligaments were severed (Desault) and in unsuccessful reduction amputation even was performed.

Petit described very accurately the luxations of the *upper thigh* in the four directions, upward and inward, upward and outward, downward and inward, downward and outward. B. Bell regarded as the most frequent kind that at the foramen ovale, which was the only one he had often seen, while the upward luxation seemed to him of very rare occurrence, indeed, almost impossible on account of the projecting rim of the socket. They abandoned reduction in the exact direction of the thigh, which had by that time brought into use every kind of instrument of torture, and they recognized the necessity of a flexion of the femur at a right angle, to which Hippocrates had already referred (Kirkland and Pouteau). Indeed, Anderson increased the flexion to an acute angle, and in that way set inward, outward and backward luxations (1775). It is well known that seventy years later Fischer of Cologne insisted anew upon this acute angular flexion. When the muscles were badly strained, especially in long-standing luxations, Vermandois anticipated much from a gradual extension exercised by appliances, but Richter was doubtful of success. In luxation of the *patella,* while Benjamin Bell considered an inward direction as the more frequent, because the inner condyle of the femur is lower than the outer, Richter found that when the luxation occurred in riding the patella was always dislocated outwardly. The occasionally great difficulty in setting such a luxation is shown by one case in which Sabatier abandoned his efforts at reposition and called upon Boyer for help. The German surgeon, Schneider, saw the rarely occurring luxation of the *lower leg* (*Chir. Gesch.*, 9. Theil, 1781); the femur condyles were behind and below, the tibia in front and above, and the leg was shortened three inches, so that the soft part behind was so strained that a laceration was feared; the reduction followed easily. Bromfield corrected the dislocation of one of the two crescent-shaped cartilages in the knee joint by alternately flexing and extending the foot gently. In a complicated luxation of the *talus,* in which it was torn loose and forced into the wound, Laumonier and Desault extracted the bone successfully. *Congenital luxations* of the hip and shoulder joints, mentioned by Hippocrates, are described by J. L. Petit and Heister, and by Verduc, who regarded the attempts at reduction as an evidence of unskilfulness of the surgeon. Löffler of St. Petersburg published a work on diastasis of the bones ("Richter's chir. Bibl.," xiv S. 301 1795).

The field of *inflammation of* [illegible] ntirely fallow until within the secc [illegible] tury. Here, also progress first arc [illegible] except one of the most precious discoveries of the century, the resection of the joints, introduced by White in the year 1768 (see chapter xx), we find as the most conspicuous publications, the works on coxitis, by Edward Ford, and on tumor albus by B. Bell. *Coxitis* was at that time very often mistaken and treated unsuitably. Ford ("Obs. on the Disease of the Hip Joint," 1794) traced it to caries, since for a long time this inflammation of the joint was regarded as a form of disease pertaining exclusively to the hip joint. From twenty histories of cases at hand he described with great accuracy especially the first symptoms, which had hitherto always been overlooked. The child grown tired and pale, feels a slight lameness and soon begins to limp. The affected leg is longer than the healthy one, his buttock flattened and an often very severe pain appears in the knee, an extremely important symptom which, unfortunately, often gives rise to errors in diagnosis. In standing, the patient bends the knee joint somewhat and supports himself only on the point of the foot, and in the dorsal position the leg is bent and every effort to straighten it is painful. The region behind the large trochanter and that in the vicinity of the groin become sensitive. With the appearance of suppuration begins a second period, in which the pain and swelling increase and the limb becomes shorter. This condition lasts for a varying time, until the abscess breaks and hectic fever and death ensue. Then in postmortem one finds the head and neck of the femur, the socket of the joint and its vicinity carious. If the abscess does not break, which, however, is very rarely the case, the patient recovers from it with an ankylosed limb. The caries of the joint can be very considerable before the external symptoms indicate it; it is the actual cause of the disease, not the consequence of suppuration. Pain in the knee, elongation and atrophy of the thigh and pain on moving the joint distinguish it from a psoas abscess; not the bending of the thigh and the flattening of the buttocks, which are common to both diseases. A multitude of unsuitable internal and xternal remedies were previously recommended for coxitis. Ford favored baths of warm sea water in the first stages, but never after the appearance of suppuration; the most efficacious was the douche. Bleeding and dry cupping were employed only at first, never when caries was actually present, and it was doubtful if caries could be prevented by blisters. For the most part Ford recommended large issues with twelve to fourteen peas outside of and somewhat behind the large trochanter, and he discarded hot irons and the moxa as too painful, and likewise the seton. He saw many patients recover the complete use of their limbs under an issue. The opening of the abscess or the acceleration of its breaking was entirely opposed, as usually the most dangerous conditions follow that event closely, especially in cases of wide incisions or the insertion of tents. The pus might possibly be absorbed and the patient saved with an ankylosis; moreover, in case of spontaneous opening, the mouths of the fistulæ are so small that the patient is not suddenly exhausted. Ford regarded a certain resoluteness necessary to withstand the pressing demands of the patient and relatives to open the large, manifestly ripe abscess. Not a word could be said of an amputation, as the caries was usually more severe in the socket of the bone than on the ball of the femur. In threatened caries of the joint he considered ankylosis as the most favorable outcome; surgery could not reach it, but only medical treatment, which required for the strengthening of the constitution, first of all, nourishing diet, fresh air, cinchona and opium. It appeared to him worthy of note that caries of the joints of the upper extremities was, as a rule, more easily cured and less frequently fatal than that of the lower extremities, because the lower limbs could only with difficulty be kept in continuous and absolute repose, and the patient must do without movement and fresh air. *Gonorrheal* inflammation of the joints was described in detail by Musgrave in 1723.

Chronic inflammations of the joints were placed in one group and given the name fungus articuli, white swelling or the designation applied by Wiseman, tumor albus (white swelling 1734). The work of B. Bell ("A Treatise on the Theory and Management of Ulcers with a Dissertation on White Swellings of the Joints," 1778) was most accurate, but Brambilla's treatise (1787) was without scientific value. Bell distinguished rheumatic from scrofulous white swelling, and in brief, in the following manner: In rheumatic white swelling the ligaments of the joints first suffer and swell, and later the bones, which sometimes become carious; the pain extends immediately over the entire joint; the swelling, also at first considerable, is located in the soft parts; usually in young people arising after injuries, which form is curable. In scrofulous white swelling the bones suffer first. Their joints swell, and become spongy and the cartilage disorganized; later the soft parts are affected. (Dörner of Tübingen endeavored to prove, by experiments in 1798, that cartilages of the joints could not become inflamed.) The pain is at first limited to a single small place; the swelling, at first slight, evidently proceeds from the bones. This form, arising spontaneously in dyscrasic people, is almost always incurable. In rheumatic white swelling Bell recommended cupping, blisters and mercury salve (Pott and Ford the fonticulus, and Kirkland cold water), and for the stiffness remaining, the rubbing with olive oil; in threatening caries nothing but amputation will suffice. He knew of no remedy for scrofulous white swelling and even regarded amputation as useless. If the dispersion of the suppuration of the joint failed, Kirkland evacuated the fluids through a very small opening, endeavoring to avoid the admission of air and to accomplish a prima intentio. Instead of amputating he applied resection according to Park's suggestion. Douches of warm water, for stiffness, were first recommended in France (le Dran, Bell and Aiken), and of water of lead (Goulard), also of chalybeate water and decoctions of finely divided herbs which were allowed to fall from a height of four stories (Thedens). Besides douches of fluids, hot fine or coarse sand or small stones were similarly used (Pouteau in sciatica). The all-curing electricity was not allowed to be lacking in the overcoming of stiffness of the joints. (In the eightieth year of the century Maudayt of Paris and Birch of London were specialists in this branch, and their widely extended activity resulted in the use of electricity in all possible ailments, rheumatism, paralysis, persistent swelling after fractures, luxations, sprains, amaurosis, ophthalmology, old ulcers, chilblains, deafness, toothache, dropsy, epilepsy, inspissation of milk, suppression of menstruation, pollution, etc.)

Heister distinguished *dropsy* of the joint from white swelling, only by the fact that in the former "the fluids collect in the joint itself, in the latter they stagnate outside of the joint." Hydrarthrus of the knee gave the surgeons slight concern; if they did not succeed in dispersing it, then, according to the example of Würtz and Purmann, an incision was made and the water let out; the operation was opposed only in case of old and large swellings and delicate patients. In order to prevent a new gathering Purmann had a vulnerary water injected into the cavity of the joint, which Heister recommended, or according to Würtz a tight bandage was adjusted around the knee. Even the intelligent O. Acrel, after an unsuccessful attempt to scatter the fluids, made two crescent-shaped incisions on the knee, and had the good fortune to cure his patient without any ill consequences. As one of the first to raise a warning voice, Richter, well knowing that inflammation and fatal suppuration might follow a large incision, permitted only a puncture by means of a trocar under the displaced skin. B. Bell went one step farther. He discarded the operation entirely, even if the other means, as rubbing, douches, plasters and envelopment did not allay the swelling; the consequences of the operation seemed to him much more serious than the pain of the patient if the swelling were left to itself. Mohrenheim gave "strengthening injections" when the effusion of water continued after the incision, and Gay, a surgeon at the Cape, first made alcoholic injections through an extended trocar puncture (1789). In case of the gathering of blood or pus, Bell also ordered an evacuation as soon as possible, by means of the trocar; Theden once lost a patient with hemarthrus in the knee, when, after opening, repeated hemorrhages, as much as seven pounds in one day, ensued. Our acquaintance with *loose bodies in the joints* we owe to A. Paré who, in 1558, cut "une pierre de la grosseur d'une amande" out of a knee, with success; seven years afterward the German physician Wagner found such a one in the joint of an ox. Views differed greatly as to the manner of their origin; they were regarded as a precipitate from the synovia, analogous to bladder-stone (Paré), as pieces separated from the cartilages of the joint or from the bone (Monro, Mohrenheim and Löffler), loosened formations of cartilage (Ford, and similarly Desault), scirrhous synovial glands (Theden), transformations of a part of the synovial membrane into cartilage (Bichat). J. Hunter considered them as originally extravasated blood which had become organized, assumed the nature of the part with which it was connected and, by rubbing, had gradually become separated from it. This view, later renounced, was supported anew by Velpeau. The pieces of the loose bodies varied much in length (Theden, three inches), and also in number; for example, E. Home had seen, in a pseudoarthrosis, thirty or forty loose bodies of a cartilaginous or harder character in the newly formed capsular cavity. Surgeons were not united as to the indications for excision, of which method we have spoken in the previous chapter. B. Bell would only cut out the movable cartilage when it was entirely loose, movable and the pain very severe; when immovable he either did not operate at all, or if the pain was unbearable he preferred amputation, because in such a case the inflammation following excision is of unusual severity. On the contrary, Desault did not at all avoid this operation so long feared by practitioners. When previously the surgical axiom was accepted, which considered wounds in the joints as, if not fatal, then extraordinarily dang[illegible] ac[illegible]nt of the admission of air, he showed that treatment they were rarely accompanied by serious complications and therefore the operation for bodies in the joints, methodically performed, could have no injurious consequences. In order to avoid the operation Gooch endeavored to hold the movable cartilage firm by a bandage in a position that was not painful. A case described by C. C. von Siebold under the diagnosis "lameness" ("Chir. Tageb. Beob.," xiv, s. 35) gave weight to the *joint neuralgia*, first described by Brodie (1836); an unmarried person, of 30 years, who had suffered from suppression of her menses, had uninterruptedly, day and night, for six months, the severest pain in her right hip and could no longer stand. Salves and plasters were without avail until a copious bleeding, with purgatives, restored her so far that she could walk without crutches, but limped badly. Siebold assigned as the immediate cause of the difficulty a congestion of blood at the hip joint, upon which an obstruction of the smallest blood vessels in the synovial glands and ligaments, and a deficiency of synovia followed.

(To be continued.)

SOCIETY PROCEEDINGS.

Mississippi Valley Medical Association.

The twenty-third annual meeting of the Mississippi Valley Medical Association held in Louisville, Ky., October 5 to 8, was a signal success in every respect and will pass into history as the banner meeting. The Committee of Arrangements, with H. H. GRANT, M.D., as chairman, had the affairs of the reception well in hand before the meeting. There were so many papers offered on the program that it became necessary to hold the meetings in two sections, a medical and surgical. The general sessions and the medical section were held in Liederkranz Hall and the surgical section in the Scottish Rite Hall immediately next door. The Committee felt much chagrined that the acoustic properties of the Liederkranz Hall proved so poor when only partly filled, as was the case when the general meeting divided for section work. This proved quite annoying, at times necessitating poor ventilation when the windows were closed to shut out the outside noise.

A feature of the meeting was the exhibit hall, in the basement of Liederkranz Hall. Here, attractively arranged, were some twenty-six exhibits representing all branches of mechanical, instrumental and therapeutic appliances, the hall being crowded all the time.

The general sessions and the medical section meetings were presided over by THOMAS HUNT STUCKY, M.D., of Louisville, president, and the meetings of the surgical section by the first vice-president, C. A. WHEATON, M.D., of St. Paul, Minn.

On the morning of the first day, after the preliminary exercises, Dr. Stucky read his presidential address, which dealt with a brief history and mention of the physicians that the Mississippi Valley had given to the world and who had become famous. He paid a feeling tribute to the late Edward R. Palmer, who met such a sad and untimely death.

At the first meeting a revised constitution of the Association was read, it coming as a recommendation from the Executive Committee, which had met the evening before. The changes were radical in some respects, providing for the perpetuation of the Judicial Council, making it *obligatory to pay all dues and providing for the dropping of members for the non-payment* of dues for two years; providing for the payment of a small salary to the secretary and for the publication of a volume of "Transactions." These recommendations were adopted on the last day.

Governor BRADLEY [illegible]de the address of welcome on behalf of the State and [illegible] BAILEY, M.D [illegible]lf of the physicians of Lo[illegible]t this ti[illegible] rumor became current [illegible]iana h[illegible]ran-tine against Ken[illegible]act [illegible]ad or[illegible]ates [illegible]r d[illegible] from Governor Bradley to the Governor of Indiana and also from a committee from the Association composed of Drs. I. N. Love and C. A. Wheaton. This message was in the form of a resolution offered the Association, and was seconded by W. N. Wishard, M.D., of Indianapolis and A. P. Buchman, M.D., of Fort Wayne, Ind. The next morning C. W. Brayton, M.D., of Indianapolis offered a resolution recalling what passed the day before, as it had since been ascertained that there was needless apprehension and that no quarantine had been declared. This was referred to the Executive Committee, which made some changes therein and, as reported, it was passed and sent to the Governor of Indiana.

Dr. John V. Shoemaker's address was entitled, "Progress and Problems of Medicine."

He first took up the subject of organo- and sero-therapy, and pointed out the extent of progress of science in furnishing effective serums and antitoxins for the cure of infectious disorders. Passing briefly over the yellow fever organism and the use of the Roentgen rays, Dr. Shoemaker took up the subject of cancers, the cause and treatment of which he stated were the most difficult problems of medicine. The only recourses to effect a cure, he stated, are the knife, caustics and electricity. None of these in the minds of the learned physician had satisfactorily solved the problem. The urgent desideratum was a method of arresting a malignant growth and causing its retrogression or expulsion. Among the methods employed the speaker mentioned the application of sero-therapy, the use of erysipelas toxins, methyl violet and methylene blue. Celandin, the remedy brought forward by Denissenko, had proved inefficient. In speaking of malaria, Dr. Shoemaker said that the life history of the parasite is not known outside of the human organism. He believed that the mosquito had much to do with its trans mission. He called attention to the fact that chronic malaria was becoming a potent agency in the genesis of various affections, producing anemia, cardiac excitability, neuralgia, neuroses and organic affections of different kinds. Concluding his paper, Dr. Shoemaker said: "Eleven years ago, in an English city and at a meeting of English physicians, I listened with shame and indignation to an American belittling his country. Various alleged shortcomings were exposed, and the evil influence of malaria upon intellectual development was depicted. A map, shaded to represent the prevalence and fatality of malaria, was exhibited, and the astounding statement was made that malarial intoxication was incompatible with scientific acquirements. I looked upon the map, and behold! the greater part of the United States was under a portentious shadow. In the north and east and in the northwest the gloom was lightened in a comparatively small area, but the great Mississippi Valley was shaded in the darkest hue. Almost the whole south, in fact, was included in the same condemnation, for the dark shadow ran down along the Atlantic seaboard. It is true that within the malarial districts McDowell, Sims, Gross and Campbell lived and labored, but these men, only four in number, were exceptions and exceptions proved the rule." Controverting this statement Dr. Shoemaker mentioned among the men who were reared in the malarial belt and who became conspicuous in the higher departments of human activity, Henry Clay, Andrew Jackson, Thomas H. Benton, Prof. Samuel D. Gross, "The Nestor of American Surgery," John C. Calhoun, Abraham Lincoln, Jefferson Davis, James K. Polk, Garfield, Hayes and McKinley, Gen. William Harrison, Daniel Drake, John T. Hodgen, Robert Battey, Crawford K. Long, and Samuel M. Memiss.

The address of John B. Murphy, M.D., on surgery, entitled "Ileus," was a masterly effort and was listened to with the closest attention by a large audience.

A noticeable feature of the meeting was the small number of papers that were read by title and the fact that during the meeting every paper was called for in both sections, which shows how well the scientific part of the meeting was cared for.

There were no night sessions of the Association, the evenings being taken up by informal private entertainments on the evening of the first day and a reception on the second evening, with a "smoker" on the evening of the third day. At the reception and the smoker the services of Col. Wm. Visscher of Chicago were enlisted for the entertainment of the guests, a collation being served at both.

When the report of the nominating committee was read some discussion took place as to the place of meeting recommended by the committee, viz., Nashville, which was opposed by N. C. Scott, M.D., on the grounds of exorbitant charges on the part of the hotels in the city during the meeting of the American Medical Association there some years ago. After some discussion the report of the committee was adopted by a vote of the Association, and the time of meeting placed the second Tuesday in October, 1898. The officers elected were as follows: President, John Young Brown, M.D., St. Louis; first vice-president, A. P. Buchman, M.D., Fort Wayne, Ind.; second vice-president, A. J. Ochsner, M.D., Chicago; secretary, Henry E. Tuley, M.D., Louisville; treasurer, C. A. Wheaton, M.D., St. Paul, Minn.

The official button given each member who registered was a sterling silver one containing the words, "Mississippi Valley Medical Association, Louisville, Ky., 1897," and in the center a splendid reproduction of the steel engraving of Ephraim McDowell, with the name beneath. The effect of the oxidized background and the bright lettering was very effective, and the button was cherished by all as a valuable souvenir of a most enjoyable meeting.

New York State Medical Association.

The New York State Medical Association held its fourteenth annual meeting at the Mott Memorial Hall, New York City, October 12, 13 and 14. There were also two night sessions and one of the afternoons was given entirely to the discussion of hospital and dispensary abuses. To this last the following contributed either by person or debate: Drs. F. E. Stewart, F. H. Wiggin, Wickes Washburn, J. E. Janvrin, Thomas H. Manley, J. R. McGregor, Nelson L. North, Thomas J. Hillis and John Shrady. A notable incident was the appearance of Mr. J. Harsen Rhoades, long identified with public charities in most of their forms. The burthen of his defense was that physicians themselves were the chief offenders, and that too with a disposition to shift the responsibilities upon others. Certainly there was every desire on his part to redress these grievances, but how without a delegated power. A breezy paper on "Medical Expert Testimony," by Homer O. Jewett, M.D., of Cortland County, attracted much notice in the light of certain recent procedures, and it is hoped will prove a factor in reform. The program was long, varied and in the main, as is usual with this Association, carried out to the letter. The presidential address by Charles Phelps, M.D., was suggestive and worthy of appearing in print long before the issue of the elegant although somewhat tardy "Transactions." Drs. E. D. Ferguson and Joseph D. Bryant contributed to the growing literature of appendicitis and also F. S. Dennis, M.D., a well considered paper on "Tetanus." The third day, the morning, with the exception of a paper on "Pyothorax in Children," by Douglas Ayres, M.D., of Montgomery County, was given up to gynecology and obstetrics, in the discussion of which the names of the following appeared: Drs. Charles H. Glidden, William H. Robb, Martin Cauana, George T. Harrison, C. C. Frederick and Ely Van de Warker. Among the topics of interest we can not omit to mention, "Acute catarrh of the middle ear as a sequel of la grippe" by Samuel Wesley Smith, M.D.; "Studies on typhoid," by Henry C. Boswell, M.D.; "Further notes upon the operative treatment for infantile paralysis," by S. E. Milliken, M.D.; "Stricture of the rectum," by W. S. McLaren, M.D., of Litchfield, Conn.; "A case of otitic brain abscess from chronic otorrhea; opening of mastoid and skull; recovery," by Frank S. Milbury, M.D.; "The surgery of tuberculosis of the peritoneum," by Parker Syms, M.D.; and "Traumatic paralysis of the upper extremities," by John F. Erdmann, M.D.; "A new intra-ocular iris scissors," by H. W. Wandless, M.D., of Dallas, Texas; "General considerations concerning auto-intoxication," by H. A. Haubold, M.D.: "Symptoms noted during the interparoxysmal stage of hysteria," by William D. Granger, M.D.; "A study of alcohol, tobacco, tea and coffee and their effects in nervous disorders," by Charles E. Lockwood, M.D.; "Massage as an occupation for the blind," by Arthur Y. Bennett, M.D.; "The effects of poisoning," by Morris W. Townsend, M.D.; "Tuberculosis of the tonsil," by Seymour Oppenheimer, M.D.; "A case of elephantiasis of the vulva, with specimen," by William P. Finder, Jr., M.D.; "The new epoch in the study of neural pathology," by W. A. Van Gieson, M.D.; "The conservative surgical treatment of fibromyoma," by E. E. Montgomery, M.D., of Philadelphia; "Some remarks on ovarian surgery," by A. Palmer Dudley, M.D. Such a program, even without the usual annual summary of materia medica, pharmacy and therapeutics by E. H. Squibbs, M.D., could not but satisfy the most fastidious.

The matter regarding the pledge of the Association to subscribe $2,000 toward the erection of a statue in Washington to

Benjamin Rush, the "surgeon of the Revolution," was taken up. The treasurer, Dr. E. D. Ferguson of Troy, stated that there was a surplus of $3,500 in the treasury, for which there was no immediate use, and favored an appropriation of the $2,000 instead of subscription by the members. After some discussion it was unanimously voted to follow this course, and the treasurer was instructed to send that amount to the committee promoting the monument. The following were elected officers for the ensuing year by acclamation: President, Douglas Ayres of Fort Plain; vice-presidents, second district, C. E. Fritts of Hudson; third district, H. W. Carpenter of Oneida; fourth district, C. C. Frederick of Buffalo; fifth district, N. W. Leighton of Brooklyn; members of council—first district, W. H. Robb of Amsterdam; second district, E. M. Lyon of Plattsburg; third district, W. L. Ayer of Owego; fourth district, Z. J. Lusk of Warsaw; fifth district, J. G. Truax of New York. A committee composed of F. H. Wiggins, S. B. W. McLeod, Parker Syms, A. H. Hubbell and E. D. Ferguson, was appointed to act in co-operation with other societies in an effort to bring about the passage of a law looking toward the correction of hospital and dispensary abuse.

SELECTIONS.

An "Oxygen Home" for the Treatment of Wounds.—The *Sanitary Record* says: Some weeks since we announced that some remarkable cures had been effected under what is termed "oxygen treatment," and that to extend the scope of the experiments a home was to be opened in London to test the system more fully. . . . An "Oxygen Home" was opened at No. 2 Fitzroy Square by the Princess Louise, Marchioness of Lorne. We may remind our readers that the system owes its origin to Dr. George Stoker, who, when serving in the Zulu War, observed that the natives always carried their wounded as far up a mountain side as possible, and that the altitude of this *al fresco* hospital appeared to have a wonderful effect in bringing about rapid recoveries. This led him, on his return to England, to undertake experiments in treating wounds with oxygen gas, and these have been singularly successful. Princess Louise witnessed the treatment in operation, as on most of the beds there was a specially constructed box, with glass sides, in which the wounded limb was kept in an atmosphere highly charged with oxygen. Thus the progress of a wound can be closely watched without the irritation of winding and unwinding bandages. Briefly, the treatment is as follows: "The oxygen acts in one or more of the following ways: By diminution of irritation, as any dressing applied to an open sore causes more irritation than a mixture of oxygen and pure air, while at the same time the oxygen stimulates, and not improbably oxidizes the toxins produced by micro-organisms in the surface of the ulcer. These and other points are under investigation, but enough is already known practically in favor of the oxygen treatment to fully establish its value."

The Sound Therapeutics of the Good Samaritan.—In a recent debate in the British Parliament, on the Græco-Turkish imbroglio the action of Greece in coming to the rescue of her Cretan compatriots was likened by the leader of the opposition to that of the good Samaritan who relieved the wounded victim of highway robbery after the priest and Levite, typifying the concert of Europe, had passed by unmindful of his sufferings. With the political application of the parable we have nothing to do any more than with the retort of the leader of the house that the good Samaritan would not have been admired for eighteen centuries if as a result of his intervention he had added largely to his personal estate. Our interest in the parable lies in its medico-legal aspect, in the treatment to which the wounded man was subjected and in the light it throws on first century practice. The parable, we need hardly remind our readers, comes to us on the authority of what M. Renan calls "le plus beau qu'il y ait," the most beautiful book in all literature, the work, we may add, of a physician whose familiarity with Hippocrates has been proved by Hobart and Plumptre, and whose practice seems to have lain, at least for one memorable period, in the mercantile marine of the Mediterranean. Till recently the only version of the parable accessible to English readers represented this capable practitioner as reporting the good Samaritan to have bandaged the victim's wounds, incised, punctured, or lacerated, and then to have poured into them oil and wine. That mistranslation continued to puzzle generations of the devout till the "revised version" put matters right by substituting "pouring on" for "pouring in," the authorized rendering having been adopted from a misinterpretation of the vulgate, which gives "infundens" as the equivalent of St. Luke's ἐπιχέων, though "infundo" means to "pour upon" as well as to "pour into." The good Samaritan's therapeutics are thus vindicated as conforming to the recognized practice of the time, whether Greek or Jewish. The bandage having been adjusted, it was saturated with a mixture of oil and wine, an emollient and a stimulant, presumably to keep the cloth from stiffening while rousing the reparative or healing process. It was the practice employed in circumcision, as we read in the rule: "If there is no mixed oil and wine ready, each may be added separately." Galen, writing about 130 years subsequently to St. Luke, describes a paste in which oil and wine are the principle ingredients, to be applied to wounds. The elder Pliny, whose "Historia Naturalis" was nearly contemporary with St. Luke's Gospel, refers to the same practice. The good Samaritan's therapeutics, as reported by St. Luke, were indeed *secundum artem*; and if they have caused any difficulty to the non classic reader, that has been removed by the revisionist substitution of "pouring on" for the meaningless "pouring in."—*Lancet.*

Practical Points in the Use of Milk Modification.—The *Cleveland Journal of Medicine* for August gives an account of a discussion on the above subject, in the course of which Dr. T. M. Rotch of Boston explained certain points that are not ordinarily brought forward in formal papers. In substance the speaker's remarks were as follows:

It is true that harm may be done by an inexact combination of different constituents of modified milk, but then we must take into consideration that in everything in medicine and surgery there is danger in the hands of those who do not do it properly. Physicians must learn to use the laboratory. I have seen bad results from a physician not prescribing correctly. It is not as dangerous, however, as using artificial foods and not knowing what you are using. I believe in feeding with human milk, but you have to learn how to use it, and when you can not get it you must learn how to use cow's milk.

I think in Boston they sell eight tubes, with four or eight ounces, for 50 cents. It is not a cheap food. A great deal of harm has been done by the physicians of New York, who say we *must have cheap food for the people. I think we ought* to give the best food to infants. As in everything else, you can not get a good thing cheap; you have to pay for it. As it is developed it will be made more cheaply. I have encouraged them to raise their price rather than lower it. Philanthropists in Boston, especially Mr. N. S. Kaetlett, have been getting up funds to buy modified milk for poor babies. Now the poor babies are fed just as well as the rich ones. I think physicians and surgeons ought to find and prescribe that which is best for the human race. The argument that the laity will adhere to their prepossessions in favor of the artificial food has been brought up over and over again by physicians. It is not the people's fault but the physicians'. I think we should work in the best way, no matter how we are criticised. There will for a long time to come be cities and towns where a laboratory can not be sustained.

The first step is to recognize the principle. Then carry out the principle as well as you can. The home modification of milk is fully recognized in my book. I have given precise rules how to modify milk. Supposing you are in the country with a baby with weak digestion. See that the cow is clean and milked by some one careful to see that the baby gets the last part of the milking freest from organisms. With a Babcock milk tester you can tell what is the percentage of fat in a given sample. My great-grandfather was professor of materia medica in the University of Pennsylvania and I have the pestle and mortar with which he pounded his drugs. He, for lack of an apothecary shop, modified his drugs at home. Up to the present time, owing to the lack of a milk laboratory, we have modified the infant's food at home. Now there is no longer a necessity for home modification either in drugs or milk.

There is probably some difference between the proteids of cows' milk and human milk. "Caseinogen" is a better word than "casein," which is being gradually dropped. I think that there have been a great many erroneous views held in regard to this difference. Nowhere in the world are they working on wrong principles so much as in Germany. We know that the coagulable parts of the proteids in cow's milk is greater than in human milk, therefore, other things being equal, we should prescribe a rather lower percentage in human than in cow's milk. I do not think the Germans have sufficiently proved to us any other difference. I think they are very theoretic in their treatment of this question. They have not adopted our methods. They are usually in the foremost ranks of investigators, but I do not think they are in this. I have been much interested in observing the curds in human milk and have seen them as large and heavy as in cow's milk, and on examination have found that in these cases the proteids were as high as in cow's milk. The reason you note a heavier curd oftener in cow's milk is because you do not usually get so high a proteid in human milk. In regard to the substitution of sugar for the proteids, I think it is very theoretic and do not think it is going to be supported by scientists throughout the world. I do not believe the sugar is going to be used in place of the proteids. The partial digestion I think is unnecessary, and the less tampering with the proteids before they enter the stomach the better. The infant's stomach should be taught to digest proteids and not to have them digested for it. Much work of this kind has been done in Germany, but I look upon it with profound skepticism. I do not think they are right. They are always trying to make out differences, but they never have done it. I do not think the Germans fully appreciate what we are doing in this country. They have gone so far ahead of us in some branches that it is difficult for them to think that we do anything of value here, while in fact they are far behind the times in the matter of feeding.

Tests for Defective Vision in School Children.—Instances of students who, through myopia or other ocular diseases, are unable to see reasonable distances, and who, by glasses or other treatment, find such obstacles removed; or of others, who, through hypermetropia or astigmatism, find themselves disinclined to study, owing to an overtaxed muscle of accommodation with consequent asthenopia or eye-tire, headache, etc., and who by suitably adjusted glasses are enabled to study with pleasure and comfort, are of sufficient frequency to have deeply impressed every individual engaged in educational work.

Between two and three years ago I submitted to the Minnesota Academy of Medicine a paper entitled "Refraction in Schools," proposing a procedure for the easy detection of most ocular diseases by principals, through which students might be placed upon a path leading toward relief, that impressed the Academy so favorably as to induce it to forward to the Minneapolis Board of Education a petition for its formal adoption. The board at that time, for reasons probably satisfactory to itself, practically tabled the resolution. Last January, after the election of a new board, the method was adopted and the writer appointed as superintendent. Immediately active operations were begun, and in a short time 25,696 children had been examined by our school principals. One hundred dollars was allowed for expenses, which has more than covered the expenditures, as only some test-types and printed matter are necessary. A plain lecture was delivered to the principals descriptive of ocular anatomy, physiology and refraction, with its errors, including myopia, hypermetropia and astigmatism. This was supplemented by a clinic or practical demonstration of the method on some fifty pupils furnished by Superintendent Jordan, during which the writer first made his test, distributed cards and filled in the statistical papers himself, and then requested many of the principals to do the same under his instruction. Test cards and printed matter were then distributed to the principals and they were requested to make the tests as rapidly as was consistent with their other work. The examination should not be conducted in the presence of other scholars, as familiarity with the letters leads to correct responses. It should be ascertained if the child habitually suffers from red and inflamed eyes or lids, after which the visual tests should be conducted. The Snellen test card should be hung upon the wall in a good light, uncovered by glistening glass and on a level with the pupil's head. The letters are of such accurate proportions as to be seen by a natural eye at certain fixed distances. The pupil should be given credit for the smallest line of which he reads a majority of the letters and result inscribed as 20, 30, 70, 200, etc., in the appropriate line of the statistical blank. . . . After noting the smallest line read by each eye, it should be ascertained if the pupil really habitually suffers from tired eyes or headache after study, care being taken that such troubles are not imaginary. . . . If inflamed eyes are not habitual, the pupil reads a majority of the letters in the 20 foot line with each eye and does not frequently experience eye tire and headache after study, the examination may be considered satisfactory; but if the reverse of this develops, a card of warning should be sent to the parent, urging that an "eye doctor" be consulted at his office or dispensary. The word "eye doctor" should be used, as many people do not discriminate between the words oculist and optician. The warning cards may be heeded or not, as the parent elects; it is not obligatory and imposes no hardship. The influence of the principal may, of course, be exerted in the proper direction, but such influence must obviously not be directed in favor of any particular oculist or dispensary, but should be used against the consulting of opticians at department stores or elsewhere. Children already wearing distance glasses should be tested with such glasses on the face, while those wearing glasses for close work should be questioned as to the existence of asthenopia when glasses are worn; by so doing much opposition from parents and attending oculists will be avoided. . . . Only such children as are deemed defective require statistical tabulation, the others are not further molested until the next annual examination, which should occur at the beginning of each school year. Experience has taught that it is unprofitable to examine first grade children. The report of our first annual examination shows that 25,696 children have been tested, of whom 8,166, or 32 per cent., were deemed defective. Among these, 6,451 eyes were found possessing a vision of 20-30, or a little worse than normal; 2,256 eyes had a vision of 20-40, 1,214 a vision of 20-50, 1,130 a vision of 20-70, 715 a vision of 20-100, 447 a vision of 20-200 and 43 eyes were practically blind; 4,472 children could not use their eyes to a reasonable extent without eye tire, headache, etc. The individual percentages of defectives in the different schools have ranged all the way from 11 to 67 per cent., the latter occurring in a conspicuously poorly lighted and insanitary building. What have been the practical results? These have been difficult, and in short, impossible to completely estimate, owing to many causes, of which a few will be enumerated. In the first place, such results can not be accurately compiled, for obvious reasons, unless all examinations are made and subsequently watched by a single oculist, either with or without assistants. Statistics compiled from numerous and unreliable sources are manifestly not entirely trustworthy. In the second place, many reports received by the writer from principals were very meagerly filled out. . . . The writer knows of many instances where good results followed treatment, but where such results were not duly chronicled. Then a very large proportion of defectives are delaying the consulting of an oculist from various causes—among which may be enumerated heedlessness, carelessness, incredulity, pride coupled with financial distress, fear of being advised to wear glasses, the near approach of a long vacation, during which time such matters may be adjusted, etc. Many children who are debarred from seeking proper advice from these and other causes, will naturally soon be enumerated among those who are deemed defective, sought counsel and received benefit. But notwithstanding these obstructions to progress, the annual reports recently studied, together with subsequent conferences with principals, show unmistakably that in the neighborhood of two thousand children have been signally benefited by the results of the preliminary tests. Many near sighted children unable to see blackboards, charts, etc, and debarred from comprehensively observing the world and learning its lessons, have by the aid of properly adjusted glasses been placed upon an equality with their comrades. Many children unable to study without pain and fatigue, consequent upon hypermetropia or astigmatism, have by a similar remedy been relieved of their infirmity and enabled to assume high rank as scholars. Other children have been emancipated from the mortification incident to the possession of crossed eyes by an operation, while others have been placed on the road to good vision by operative interference upon congenital cataracts. One of the chief obstacles to satisfactory results has been the frequent consulting of opticians instead of oculists. The eye is not a merely mechanical machine, which, when "out of order," simply requires for its correction a pair of glasses. It is one of the most delicate and complex organs of the body, liable to the diseases of other living structures, and extremely sensitive to improper treatment, including the adjusting of glasses, which, if improperly performed, often leads to the direst consequences. Pathologic ocular conditions, including refractive errors, can not be properly diagnosed and treated without a good medical education, supplemented by special ocular instruction, fair judgment and experience. It is, therefore, almost an insult to intelligence to urge that even the best opticians are incapable of passing judgment upon diseased ocular conditions or of properly correcting refractive errors, although they may frequently happen to give good satisfaction in recommending a pair of glasses. The truth is that in undertaking such work they are practicing medicine and should be legally restricted in their trade to selling, dispensing and manufacturing glasses, a principle which has been recently emphasized by the Ohio legislature in an act restraining opticians from prescribing glasses, under improper circumstances.—Abstract of paper by Frank Allport, *Educational Review*, Sept. 1, 1897.

PRACTICAL NOTES.

Warning Against the Use of Dry Boric Acid in Otitis Media Purulenta.—*Memorabilien* mentions that when the secretion is scanty, the powder has a tendency to form a crust with it, and close the opening.

Urine Tests in Laryngology.—Mulford mentions several cases of ear or throat trouble in which the treatment was indicated by testing the urine. The local disturbance vanished with the general treatment instituted.

Bactericidal Power of Iodoform Increased.—Thomalla of Berlin has added 5 per cent. polymerized formic aldehyde to iodoform and reports that suppurations dry up and wounds heal much more rapidly and thoroughly than with the iodoform alone.—*Semaine Méd.*, July 28.

Delirium Tremens Paraldehydicum.—Reinhold adds another to the five cases on record of acute delirium tremens produced by excessive use of paraldehyd (in his case 60 grams had been taken daily for some time to cure insomnia). The symptoms abated and absolute recovery followed in sixteen days. All the other cases also recovered completely.—*Wien. klin. Woch.*, August 5.

Cure of Vomiting in Pregnancy by Prolonged Palpation.—J. Geoffroy states in the *Gaz. Méd. de Liége*, of Sept. 2, that the vomiting is caused by reflex contraction of parts of the alimentary canal, pylorus, duodenum, secondary to contraction and hyperesthesia of the ilio-pelvic angle of the colon. Prolonged palpation reveals the existence of the contraction at this spot and is also the cure for it, rapid and certain, in one to three brief seances. He adds several convincing observations.

Nicoladoni's Suture in Resectio Recti.—The proximal stump remaining after the resection is drawn out through the anus without force and sutured to a ring made of wire wound with gauze 3 to 4 cm. in diameter. The greater part of the mucosa is removed from the distal end, and a few internal sutures then suffice to fasten the invaginated ends together. The ring allows irrigation to keep the rectum clean from fecal matters. He gives saline laxatives, never opium. Two cases thus sutured have demonstrated the advantages of the ring.—Prof. C. Nicoladoni in *Cbl. f. Chir.*, September 4.

Treatment of Chronic Constipation with Creosote.—It is announced that creosote not only breaks up the most inveterate case of constipation, but improves the general health. It acts probably, by neutralizing some toxin that has been paralyzing the nerves of the intestinal tube. Its beneficial action was discovered by V. de Holstein, who has contributed an article to the *Semaine Méd.*, on the subject (September 1). He administers seven to eight drops twice a day, after the two principal meals, in a glass of milk, beer, or water, with or without wine. He uses pure beech creosote, and commences with one drop, increasing one drop a day, until the requisite dose is determined.

A New Phenomenon observed in Facial Peripheral Paralysis, is reported by Bordier and Frenkel in the *Semaine Médicale* of September 8. The subject affected with severe peripheral facial paralysis is unable to close his eyes when requested, without turning the eyeball of the side involved upward and slightly outward. This sign indicates the gravity of the prognosis, and the progress toward recovery as it gradually disappears.

Sanoform.—P. Sternberg of Berlin, describes in the *Ther. Mon.*, July, his favorable experience with sanoform. He has used it in ninety cases, thirty-seven of them fresh wounds. The powder was applied copiously after cleaning the wound with an occlusive bandage. In two to four days the bandage was changed, when the wound was found healed in most of the cases. If necessary a second dressing was made, under which the wound healed smooth. In twenty-eight cases there was suppuration, abscesses, panaritium, etc., which were first lanced and curetted. When the bandage was changed they were found almost completely dry, and at the second change of the bandage most of them were quite healed. Fourteen cases of fissures and rhagades were treated with a 10 per cent. sanoform-lanolin salve and healed in the shortest time. Six cases were tamponed with sanoform gauze, which is sterilizable.—*Ther. Woch.*, August 1.

Acute Purulent Arthritis due to Pneumococci.— Fournier and Courmont (*Revue de Médecine*, September 10, p. 681), maintain that in addition to subacute and chronic forms of arthritis due to pneumococci, there occurs also an acute phlegmonous form, of which they describe an illustrative case. From the anatomo-pathologic point of view, three degrees of arthritis due to pneumococci may be described: 1, the mild form without macroscopic lesion; 2, the form attended with simple hydrarthrosis; 3, the ordinary purulent form; 4, the form presenting osteoarthritis with cartilaginous and osseous lesions, which occurs rather more frequently than is generally believed. In the course of arthritis due to pneumococci, death, which occurs rather frequently, is due most often to secondary generalization of the micro-organism to other serous membranes (pleura, pericardium, meninges), and rarely to the primary infection. This generalization may be attributed to impaired resistance of the soil, and to maintained virulence of the micro-organism, even after its passage through the articulation. This virulence, however, seems in certain cases to be attenuated in proportion to the multiplicity of the lesions.

Inflammatory Conditions of the Uterus, Adnexa and Pelvic Peritoneum with Intra-uterine Irrigations.—From Tomsk comes the announcement by Prof. J. N. Grammatikati, that all the above conditions are healed with the best results, even the most obstinate endometritis and gonorrheal affections, with daily irrigations for an average of forty days, with one gram of the solution: Alumnol, 2.50; tinctura iodi and alcohol absolut. aa 25.0, injected with a Braun syringe. The surrounding parts are first disinfected, the portio opened with a speculum and parts held with ball forceps; Hegar dilator used if necessary. Two grams of the solution are used in acute inflammatory conditions with exudation. The menses are arrested by fifteen to twenty irrigations and this temporary climacteric which lasts two or three months is an important factor in the cure. Neoplasms frequently subside completely with this treatment, and where a pyosalpinx still requires operating, the indications are much more accurately determined after the remarkable improvement secured by the irrigations. Many chronic cases were so much improved that an operation ceased to be necessary, and in grave gonorrheal affections the ability to conceive returned. No inconveniences were observed from this treatment in the 3,000 irrigations made in his clinic during the last three years. Transient pain in a few cases was relieved at once by repose or a morphin suppository, 0.01.—*Therapeutische Wochenschrift*, August 22.

Oil of Wintergreen as an External Application in Rheumatism.—According to M. Lemoine, local applications of oil of wintergreen are valuable in rheumatic fever, acting more rapidly in relieving pain than salicylate of soda and being less liable to produce tinnitus or giddiness, which sometimes follows the use of the latter drug. He soaks a piece of lint in two or three drams of the essential oil, and applies it to the skin; the whole is then completely covered by oiled silk, which well overlaps the lint, and carefully bandaged so as to prevent external evaporation. The application is made over the painful spot if this is conveniently situated; if otherwise, the thigh or arm is chosen. In this case the oiled silk should be long enough to encircle the limb, and the absorption of the salicylate of methyl which forms some 40 per cent. of the oil produces almost as good result as if applied to the seat of the pain. This method of treatment answers very well also in some cases of sciatica and, according to M. Siredey, in chronic rheumatic affections, where it may be used for a considerable time without any ill effects, either local or general. Here it acts better when applied directly to the affected joints than when the dressing is placed round the shaft of the bone. The strong smell of the oil is the only inconvenience. The same application has proved useful in relieving the lightning pains in a case of locomotor ataxia. The use of oil of wintergreen as an external application in chronic and subacute rheumatism is not anything novel, though the particular method of its employment may perhaps be so. Mr. J. D. Staple, however, used it in the Stockport Infirmary several years ago as a liniment combined with an equal quantity of olive oil, and reported that in only two out of a hundred cases of chronic rheumatism did it fail to relieve the pain.—*Lancet.*

The Treatment of Surgical Tuberculosis with Koch's New Tuberculin.—Eve (*Lancet*, September 18, p. 705) reports eight cases of surgical tuberculosis subjected to treatment with Koch's new tuberculin (T. R.). Three cases of tuberculous disease of joints, without sinuses or evidence of softening of caseous material, were the only ones in which favorable results were observed. Two of these were examples of early tuberculosis of the elbow and hip respectively. Of these it was thought that the same results might have been anticipated from surgical rest, improved diet, etc. In the other, occurring in a patient with relapsing tuberculosis of the knee of four years' duration, it seemed probable that the remedy exercised a favorable influence. One case was an instance of tuberculous peritonitis with ascites, which was treated immediately by celiotomy. During the administration of the tuberculin there was no reaccumulation of the fluid, but the child continuously lost weight. It was necessary to give the tuberculin slowly and gradually, owing to the weakly condition of the child, and to avoid pyrexia. The remaining four cases were all examples of tuberculosis with sinuses. These, with one possible exception, were absolutely uninfluenced by the treatment. The sinuses did not heal and in three instances operation was ultimately required. The case of a child with tuberculous tenosynovitis of the dorsum of the hand seemed clearly to show that no immunity to tuberculosis was established by the treatment. The tuberculous material had become caseous and broken down, with sinus formation, but was not, in the ordinary acceptance of the term, septic. After the conclusion of the course of treatment with tuberculin, all of the tuberculous material was freely and carefully removed by operation, no bone disease being found. The wound healed by first intention, but two or three weeks later recrudescence occurred in the scar and subjacent tissues. The exceptional case referred to occurred in a patient with tuberculous epididymitis. A sinus that remained after the opening of an abscess healed during the administration of tuberculin. The personal impressions of the results of the new remedy are summed up as follows: Some slight, although no markedly favorable, influence may be exerted in cases of early tuberculosis of joints or in which no evidence of softening of caseous material exists, but the effect when caseous material has broken down, and especially if the disease has become septic, is negative.

Recovery after Stab-wound of the Heart and Pericardium.—Williams (*Medical Record*) has reported the case of a colored expressman, 24 years old, who, during an altercation, received a stab-wound through the fifth costal cartilage, injuring the internal mammary vessels and wounding the pericardium and heart. The wound was about an inch long, three-fourths of an inch to the left of the sternum, through and in the long axis of the fifth cartilage. With a probe only a superficial wound could be made out, but during the night there was such persistent hemorrhage, pain over the cardiac area, short, sharp, shrill cough and such pronounced symptoms of shock that a re-examination on the following morning showed that the knife had penetrated the fifth costal cartilage in its long axis at least far enough to wound the internal mammary artery and veins. When the knife had been withdrawn the elastic cartilage had closed behind it, preventing the introduction of the probe the night before. Operation was decided on and the original wound lengthened to the right as far as the middle of the sternum. A second incision about six inches in length was made from the center of the first and carried over the middle of the cartilage and fifth rib. The sternum, cartilage and about one inch of the fifth rib were exposed. The cartilage of the fifth rib was separated at its junction with the sternum and at a point two and a half inches from the sternum and one-fourth of an inch from its attachment to the rib. The inferior attachments of the incised piece were separated, leaving the superior ones in place. The incised piece was reflected upward, making an opening about two inches long and one and a half inches wide, bringing the internal mammary vessels into view. These vessels were ligated above and below with small catgut. This large opening permitted easy ligation and manipulation. To secure additional room an incision was made in the fifth intercostal space. The heart and lung being displaced backward, a small punctured wound of the heart about one-tenth of an inch in length and about half an inch to the right of the right coronary artery, between two of its lateral branches, was seen. The wound in the pericardium was about an inch and a quarter in length. There was no hemorrhage from the heart or the pericardium. The edges of the pericardium were held by long, smooth forceps and a continuous suture of fine catgut was introduced. Before the pericardial wound was closed it was irrigated with normal salt solution. Catgut was used in closing the intercostal and subcartilaginous wounds and silkworm gut in the cartilages and the skin. A few silkworm gut sutures were left long in the external wound, so as to permit of easy removal in case this should become necessary on account of infection or hemorrhage. A dry dressing was applied. The surgical progress of the case was not especially eventful. An effusion formed in left pleural cavity and in that of the pericardium. An incision in the seventh left intercostal space, two inches long parallel to the rib, gave exit to eighty ounces of bloody serum. There was no further complication and the patient left the hospital, well, seven and a half weeks after the reception of his injury. He was subsequently at work in the stock yards at Chicago two years later, and again three years later.

Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:
Per Annum, in Advance $5.00
Foreign Postage 1.75
Single Copies . . . . 10 Cents.
In requesting change of address, give *old* as well as new location.
Subscriptions may begin at any time and be sent to
THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 61 Market Street (Occidental Buildings), Chicago, Illinois.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, 100 Washington St., Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the *Editor*, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street (Occidental Buildings), Chicago.

Original communications are only received with the understanding that they are exclusively contributed to this JOURNAL.

SATURDAY, OCTOBER 30, 1897.

THE DEADLINESS OF THE HARMLESS.

There is an ancient sentiment of the human mind which is continually receiving unexpected corroboration from modern sources. It has expressed itself in various ages in the paradoxes that the Gods are jealous of prosperity, "Woe unto you when all men speak well of you;" " It's dangerous to be safe," etc. Self-contradictory as it appears, it has a basis in fact and nowhere has this been more surprisingly demonstrated than of late years in the realm of dietetics. Wine, for instance, was to the patriarch a thing "which maketh glad the heart of man ;" to the apostle the very life-juice of the universe, the best symbol of the blood of Christ; to Old Omar "the gift of God," "the Mighty Allah;" to the Greek, the crimson joy of the universe; but now, thanks to that distinguished band of scientists, FRANCIS MURPHY, T. DE WITT TALMAGE and FRANCES WILLARD, we know it in its true colors as a demon, an adder, a corroder of mucous membranes, the mother of murder and the grandfather of gout.

Again, what could have been more guileless in appearance, more blandly innocent in (and of) flavor, than the harmless, necessary potato, and yet after enjoying the confidence of the human species for centuries it has just recently been unmasked and denounced publicly, by no less an authority than the great Mrs. RORER, as a treacherous member of a murderous family, the Solanaceæ. Innocent as it appears, it is a first cousin of the deadly nightshade, the reformed member of a vegetable " tribe of Ishmael," and in the circus-poster language of the LOMBROSO mountebanks, "a criminal born." In spite of all the pains lavished upon its education it may "revert" at any moment and anyone who would avoid an attack of solanin poisoning is adjured by Mrs. R. to shun the treacherous tuber, and under no circumstances to imbibe more than one *per diem.* So that the real trouble with Paddy is not the potheen but the "praties." Like Mr. PICKWICK after the cricket-dinner, "It washn't the champagne, it wash the shalmon!"

Of course every person today who is half-educated knows that to indulge in the juicy grape or fragrant raspberry is simply equivalent to tempting "Providence" (the orthodox term for anything discomfortable), in the shape of an attack of appendicitis.

But worse is to come. When the denouncers of the drink demon had succeeded in dragooning us into shunning the flowing bowl and contenting ourselves with the lady-like lemon and the chastely cool soda-water, we were assured that the battle of Armagedlon was practically won and the race saved. Now, however, in the fullness of time arises another prophet from our own ranks to cry aloud and spare not, in the columns of one of our esteemed contemporaries, against the terrors that menace our national life in the increasing consumption of acid foods and drinks. According to him the situation is most serious. The depraved palate of New York City requires more than twenty-five carloads of lemons *per diem* to glut its cravings. Oranges and limes are poured in, in equally appalling quantities. "The grateful acid of the rhubarb in conjunction with binoxalate of potash, with the malic acid contained in gooseberries, currants, cherries, plums, apples and pears adds to the acidulous tide!" "Tide" is no word for it; "avalanche" is the only adequate term.

Tomatoes have "multiplied in production ten times since 1800 until, from comparative obscurity, they have reached the head of the list." And we wonder that heart disease and cancer are on the increase, both of which, as everyone knows, are due to the acid of the truculent vegetable. Sergeant BUZFUZ had indeed a gleam of deepest prophetic insight when he thundered "Chops! merciful heavens, gentlemen of the jury, and *tomato sauce!* Are the hearts of confiding females to be broken in this fiendish manner !" "Forty thousand tons of cucumbers and a million gallons of vinegar" are certainly enough to set the national teeth on edge. Even the preservatives which are added to the canned fruits are by a positive fatality "acids" too, salicylic and boracic, although no one would know it from their taste or effects, but "'tis down in the play" and adds to the general acidulous ruin. "Thirteen millions of pies per week," 80 per cent. of them acid, of course, while a fashionable dinner is "a feast of sours and a flow of acids from first to last."

And this is only the solid half of our sins of sourness, for "the realm of acid ingesta geometrically expands when we enter the domain of drinks." It is true that the floods of mineral waters give our scientist pause for a moment, but only a moment, for do they not contain acid also? Certainly, carbonic acid, and behold another nail in our coffin! In his despair he cries aloud that "the acidulous habits of the body mark a stage in civilization," this golden Victorian era is an acid age, an age of puckerings, of wry faces, of sour stomachs.

So terrible is the prospect that his reason well-nigh totters on its throne, and he detects the deadly traces of sourness in the smell of things, nay even in the very sound of words. The innocent term "ascetic," for instance, which to uninitiated ears has almost a note of sanctity, becomes to him phonetically full of deadliest significance. "The modern fashionable women are rendered not only somatically but also psychologically *ascetic*," we are assured, and the prophecy closes with this awful threat of doom, that "the coexistence of somatic and psychologic *asceticism* can no longer be ignored!"

And to think that this fearful fate is hanging over all of our ignorant heads and we can not even grasp what it means when we are told in plain English.

Would we fain know just how are these tons and oceans of acid ingesta to produce their harmful effects? By "reducing the alkaline bases and salts in the fluids and tissues of the economy," and as "the alkalinity of the blood is the measure of its germicidal capacity," one can easily see what terrible things may happen. What makes the situation so serious is that with the obstinate short-sightedness characteristic of mere theorists, all our psychologists assure us that the vegetable acids, including acetic, are promptly converted into alkaline carbonates, that all fruits and vegetables contain large proportions of sodium, potassium, calcium and magnesium in combination and *increase the alkalinity* of the blood and lymph. Not only so, but our physicians are under the same grave delusion, and insist that in scurvy, for instance, which is caused by a deficiency of vegetables and fruit-acids in the diet, the blood becomes acid and can be restored to its normal alkalinity by those acids of acids, lemon-juice or pickled limes. And to such lengths is this blind perversity carried that citrates, acetates, tartrates and even lemonade and acid fruit-juices are freely given in rheumatism and gout, cystitis or any condition in which lessened alkalinity of the blood is suspected, thus really, according to Dr. ENGLISH, adding fuel to the flames. And, of course, having once committed themselves to this position they are going to brazen it out to the end, for they unblushingly declare that the appalling "sour habit of the American stomach," next on our author's list of horrors, is produced entirely by the acids of fermentation of starches, sugars or fats, lactic, phosphoric, butyric or by an excess of HCl, none of which are in any way related to the acids of foods and drinks, but are animal and mineral instead of vegetable. But all these are of course simply instances of the absurd positions into which the scientific mind permits itself to be drawn step by step by the fatal chains of logic and necessary causation. Turn the light of common sense upon them and they collapse at once. The thing tastes acid, it smells acid, it is called "acid," it *is* acid and must inevitably turn anything sour to which it is added, even the fluids of the human body. The damage which we have done and are doing in our ignorance is simply blood-curdling to think of. "Blood-curdling"—why, there is another acid at work, and what must be the coagulating effects of this "acid tide" upon the milk of human kindness. No wonder the race becomes more cruel and wicked every day. And think of the irrepressible conflict between this overwhelming sourness and the "sweetness and light," which we are so vainly striving toward. But there is a ray of personal comfort in this for our prohibition friends. Think of all the agonies and discomforts that they have endured both personally and by proxy in depriving themselves and others absolutely of the enjoyment of the "good creature" in every form, when it was only the acid ones which they need have shunned. For no one, we feel sure, can read Dr. ENGLISH's eloquent denunciation without becoming convinced that at least two-thirds of the evil effects attributed by temperance reformers to alcohol are really due to the acids with which it is usually combined (or the human "chemicals," or the eye of the writer, or anything else *but* the alcohol).

This will at last explain why almost the only penalty to be paid by the (alkaline) beer-drinker is to become "fat and scant o' breath" after forty, while the (acid) wine-bibber lays up a future of gout, insanity and Bright's disease. Why the man who mixes soda with his brandy and Apollinaris with his whisky lives to a good old age, while the imbiber of "sour mash," champagne or gin-fizz, winds up with a private view of the pink alligator and a stomach-lining like that of a condemned boiler. The danger of the wine-cup is literally in its sparkle, for that is due to (carbonic) acid. Cassio's tragic apostrophe should read in the light of this revelation: "Oh thou invisible spirit of wine, if thou hast no name to be known by, let us call thee CO_2!" And as every free drinker will tell you the real "stingo" of the Manhattan cocktail lies in the (acid) cherry at the bottom of the glass. No wonder that alkalies relieve that familiar dark red taste in the mouth. To be alkaline is to be safe.

THE MORTALITY OF HEATSTROKE.

During the record-breaking weather of the month just ending there have been a number of prostrations from heat in some of our cities, and a consideration of sunstroke may therefore appear less unseasonable than might otherwise be the case. It is suggested at this time, however, by an article in the *Sanitarian* for

October, which originally appeared in the *Spectator*, a life insurance publication. The author, Mr. **Frederick L. Hoffman**, has analyzed the available statistics of mortality from heatstroke, and his conclusions and deductions are certainly deserving of notice and comment in a medical publication.

It is a curious fact that has not infrequently been remarked upon, that the death rate from this cause is extremely light in our more southern cities as compared with that of many of the northern ones. The statistics here given show this and something more; while the summer of 1896 had beaten the record in this respect up to that date in New York, Philadelphia and St. Louis, and in the two first named cities at least there had been up to 1896 an apparently progressive increase for a number of years back, in Cincinnati, on the other hand, there has seemingly been of late years a correspondingly steady decrease of deaths from this cause. It is evident from these facts that mere solar heat is not the only efficient factor, for, as Professor **Trowbridge** remarks, in the *Monthly Review of the Weather Bureau* for 1896, the inhabitants of Boston suffer under a temperature which is readily endured by those of New Orleans, and a personal factor, the accommodation of the individual to physical environment, must be added to that of the actual climatic conditions. His " provisional index," however, "that sunstroke becomes imminent during the summer months when the mean temperature of any one day, or of several consecutive days, becomes equal or nearly equal to the normal maximum temperature for the same period," does not appear to practically cover all the facts, as such days must occur as frequently in Cincinnati or Chicago as in New York, where the death rate from heatstroke is highest. It would seem that we should also consider other factors as well as heat alone, and as New York is the great entry port for immigration, and statistics show that the mortality as compared with the number of cases amongst the foreign born is very much greater than amongst natives, though the number of cases may not be so disproportionate, we may, as has been generally done, count acclimatization as one important factor. The Italians alone, in Mr. **Hoffman**'s statistics, appear to enjoy a corresponding immunity, but the figures given are too small for generalizations.

Acclimatization alone is, however, not a sufficient reason for the difference between the eastern and western or southern cities, and the well known and often quoted fact, that is supported also by the insurance journals' statistics, of the evil influences of alcoholic indulgences will also afford no explanation of this regional difference. Why sunstroke should be so much more fatal in New York with a maximum temperature of 94 degrees, than in Chicago with one of 98, Cincinnati with one of 96, or St. Louis with one of 100, is not entirely clear; the conditions of living, etc., are not so obviously in favor of the last named cities as to afford any ready explanation. In New Orleans and other southern towns, and possibly to a certain extent in Cincinnati and St. Louis, it may be reasonable to assume that the habits and customs are more sanitary as regards exposure to heat; the residents do not expose themselves as a rule with the same recklessness as do the laboring classes of the north, who furnish the greatest part of the victims of heatstroke, and to this it is probable that they owe in great part their immunity. But even this may be insufficient to altogether account for the fact; there may be other elements, climatic or otherwise, of which we know little or nothing, that come into play to reduce the mortality. Consideration of the local conditions is certainly inadequate to satisfactorily explain all the phenomena that are sometimes observed.

If heatstroke is due to a toxin as some have suggested, whether of external or internal origin, there is need for its careful and thorough study to check the waste of human life from this cause. There are other affections, far less fatal in the aggregate, that have claimed and obtained more attention, and there are not so very many that when not fatal are yet so disastrous in their after-effects as is this. In view of this last fact which, considered in all its aspects, is even more serious than the actual immediate mortality (though this may, as in 1896, reach into the thousands in this country), we are not likely to over-estimate the importance of this accident.

THE BACTERIOLOGY OF WHOOPING COUGH.

While it is generally agreed that whooping cough is an infectious disease, there is as yet no agreement as to the specific micro-organism to which etiologic activity can be attributed. Such organisms have been described by **Burger** (*Berliner Klin. Wochenschr.*, 1883, No. 1); by **Afanassiew**, who in 1887 isolated a bacillus; by **Ritter** (*Deutsche Med. Wochenschr.*, 1892, No. 45, p. 1020), who found in the bronchial secretion a diplococcus, and by **Kurloff** (*Centralb. f. Bakteriologie*, Vol. xix, Nos. 14 and 15), who isolated a ciliated ameba. It is still a matter of doubt which, if any, of these is the actual cause of the disease.

To these contributions to the subject another has been recently added by **Czaplewski** and **Hensel** (*Deutsche Medicinische Wochenschrift*, 1897, No. 37, p. 586), who describe the isolation of bacilli corresponding in some respects with those observed by **Burger**. The observations were made with fresh sputum, obtained directly after a paroxysm of coughing. The more dense flocculi were selected and washed with agitation not less than thrice in tubes containing peptone-water to remove the more gross contaminations. Streak-preparations were then made and stained with diluted carbol-glycerin fuchsin or with diluted carbol-fuch[illegible] F[illegible] ultivation, LER's serum in Petri dishes was employed. The micro-organisms isolated by these means proved to be small, slender bacilli with rounded extremities. They resembled in several respects influenza bacilli, from which they differed, however, in growing upon ordinary culture media. They varied considerably in size.' The smallest bodies resembled cocci, and those in process of division diplococci. The developed bacilli are two or three times as long as thick. In cultures, less commonly in the sputum, the organisms were joined in more or less long filaments. In their morphologic variability they resembled plague bacilli, which, however, are much larger. They are immobile, and permanent forms could not be made out. The bacilli can be stained with ordinary aniline colors and by GRAM's method. They are usually found in the sputum in large numbers in severe cases of whooping cough. They are principally free, but less commonly enclosed within cells. At the beginning of the disease bacteria are present in small numbers and are to be found only with great difficulty. When the sputum is not washed thoroughly other bacteria are found, the presence of which interferes with the development of the organisms in pure culture. Experiments upon animals have thus far proved unsuccessful. The organisms described are believed to be the cause of whooping cough, having been found in all of the thirty cases examined. This assumption was strengthened by the discovery of the bacilli in several cases at the time unrecognizable clinically as whooping cough, but which subsequently developed the disease. The organisms described were found in the nasal secretion. Further, one of the authors was seized during the progress of the investigation with severe coryza, accompanied by constitutional disturbance and slight cough, on one occasion paroxysmal. The whole attack lasted but one week, but the organisms in question were repeatedly found in the nasal secretion, apparently in pure culture.

ON RETROPERITONEAL AND PERIRENAL LIPOMA.

As is well known, the fat normally present around the kidneys is liable to overgrowth when these organs are diseased; especially when the kidney has undergone atrophic changes is an apparently compensatory hyperplasia of fat liable to occur—compensatory in the sense that it replaces the loss of volume due to the shrinking of the kidneys. But there is another form of overgrowth leading to the development of large neoplasms in which the kidneys primarily seem unaffected. Prof. J. GEORGE ADAMI, of Montreal, has recently subjected the instances of this form of tumor reported in the literature to a careful study and added two cases of his own.[1] This article must be considered as timely because there does not exist any general résumé, in our language, of this form of abdominal tumor.

Prof. ADAMI's first case occurred in a man 45 years old. It concerned a huge retroperitoneal lipoma which presented areas of mucoid degeneration and in other parts a structure resembling sarcoma. The tumor weighed no less than forty-one pounds; the left kidney was imbedded in the growth, the ureter passing down along the back of the tumor, the right kidney being unaffected. Death occurred, after symptoms referrable to the abdomen had existed for about eleven years; during the last weeks of life large quantities of pus were removed by repeated aspirations, in all about sixty pints. An exploratory laparotomy had been made, but the relations of the solid tumor, occupying practically the whole abdominal cavity, did not warrant any attempts at removal (Dr. SHEPHERD).

The second case occurred in Brooklyn under the care of W. W. BROWN, the specimens being deposited in the Army Medical Museum at Washington. A slowly growing abdominal tumor existed for two years before death, which resulted from acute pulmonary disease. At the autopsy an irregularly flattened tumor, weighing forty-one and a half pounds, was found adherent to posterior peritoneal wall and exerting marked pressure on the abdominal viscera and the diaphragm. The descending colon passed over the growth and the left kidney was imbedded in and firmly fixed by adhesions to the tumor. Microscopically the tumor consisted "largely of adipose tissue in a voluminous stroma of embryonic connective tissue with abundant nuclei between the fat cells."

ADAMI found forty similar cases recorded in the literature. The most important previous contributions are those of TERILLON[2] in France, who collected fifteen cases, and by JOSEPHSON and VESTBERG[3] in Sweden, who analyzed thirty cases.

As to the primary seat of origin of these huge lipomas exact statistics can not be given. ADAMI divides them into those of peritoneal origin, those whose origin was doubtful, and into those which appeared to have originated either in the mesentery or its root. About one-third of the cases may reasonably be described as having a perirenal origin; the largest collection of retroperitoneal fat occurs physiologically around the kidney and here is a most likely place for retroperitoneal lipoma to begin. The condition is more frequent in women than in man, in the proportion of 25 to 16. The tumor occurs almost exclusively in middle and late life, but in LAUWER's[4] case the growth was recognized fourteen days after birth and "growing steadily, attained such a size and led to so much emaciation, that when removed at the age of seven, it weighed six pounds, or almost a third of the total weight of the child after its removal (twenty pounds).

The rate of growth of this form of tumor is slow.

---

[1] Montreal Medical Journal, January and February, 1897.

[2] Arch. Génér. de Méd., 1886, p. [illegible]

[3] Hygeia (Stockholm), lvii, 1895, p. 209.

[4] Josephson and Vestberg, l.c.

On an average between two and three years elapsed between the first recognition of the tumor and removal, or death of the patient. In some cases the growth was observed for five, seven, eight and even twelve years. The size attained in the majority of the cases exceeded twenty English pounds, in weight; many were above forty and fifty pounds and one weighed sixty-three pounds.

The general disturbance is slight. Case after case is recorded without pain or disorder of the intestinal or urinary functions. As the end approaches pain may shoot down the extremities and edema of the legs may develop. Extreme emaciation and dyspnea are common features.

The definite presence of fluctuation has frequently led to diagnostic errors. Ascites, multilocular ovarian cysts and echinococcus cysts are examples of false diagnosis. A fluctuating abdominal tumor of the abdomen from which repeated puncture fails to draw fluid should lead one to think of lipoma.

The divergent descriptions of the histology of these growths are easily reconciled by the fact that every member of the group of connective tissue tumors may pass into or show areas of metaplasia into other members of the group. Hence all forms of mixed mesoblastic tumor tissue may be met with in varying proportions. True fibro-chondro-osteo-lipoma may occur.

In the forty-two cases, twenty-six extirpations, complete or almost so, were made with success in twelve cases or 46.1 per cent. In general the huge mass peels out with fair ease, though accessory lobules often have to be removed after the main mass has been shelled out. Recurrence is rare. In most of the fatal operations death may be attributed to the cutting off of the blood supply of the overlying intestine, followed by gangrene. When possible the tumor should be removed by lateral or lumbar incision. If this is impossible without gross injury to the peritoneum then free excision of the overlying intestine must be made as has been done in several cases.

In recapitulation: A retroperitoneal lipoma may be suspected when there is a very slowly growing tumor oftener situated more toward one side, accompanied by no special symptoms except progressive emaciation and eventual dyspnea, crossed by a length of intestine, and giving a sense of fluctuation, from which, further, repeated puncture fails to draw fluid. Successful operation presupposes the preservation of the blood supply of the intestine crossing the tumor; if the supply of blood is endangered resection of the intestine becomes necessary.

THE REFORMATION IN ENGLISH SPELLING.

A valued correspondent invites our attention to a letter by Mr. ROBERT BARNES, and another by Dr. JOHN WM. MOORE, both on the subject of "Reform in the spelling of the medical vocabulary," in the venerable London *Lancet* of October 2. Both these writers deprecate any change in the sacred diphthongs, and inasmuch as these were used in the original Greek, according to Dr. MOORE, we must continue to use them. This would all be very proper if we were speaking Greek, but as we are speaking English, we do not see why it is any more difficult to trace the etymology of a word in the one case than in the other. Even in Dr. MOORE's letter it is shown that "empyema" was the spelling of the word, and therefore instead of deviating from archaic models, we are simply returning to them. What about the Greek words that are from the Sanscrit? The same argument logically applies, and at the last we must, if etymologic exactness be required, go back to the Egyptian and Assyrian hieroglyph.

Moreover, it is of no use for the brethren to waste their time in fighting for the reinsertion of letters which time has shown to be obsolete and which simply add to the difficulties of English and accomplish nothing; we might as well return to the spelling of CHAUCER and SPENSER for ordinary English words. The English language has grown by evolution, one might say by excision. As we have before pointed out, nobody now spells thigh "thighe" or leg "legge," and yet this was the mode of spelling during the first half of the 16th century. We suppose that many learned heads were shocked at the dropping of the letters, and Dr. MOORE himself admits that "changes are constantly taking place and will in the future take place." Some of our transatlantic brethren still retain the u in "labour," "ardour" and "colour," and the k at the end of the word "musick," but we doubt if the Americans have time, much less inclination, to reinsert these superfluities, and if the Americans are a little faster than the English and have adopted these reforms more quickly, it is not from any disrespect to the language, nor the source from which it is derived, but from a desire to economize time, labor, material and money. Then, if the Americans can improve the language by pruning its excesses and eccentricities, the Englishman should at least rejoice with us in the establishment of a more modern language in which he need have no part.

THE NEW YORK STATE MEDICAL ASSOCIATION.

The annual meeting of this society was held in New York October 12, 13 and 14. The most interesting part of the meeting was the discussion of the abuses of medical charities. Dr. WIGGINS opened the subject with a startling array of figures from Dr. STEPHEN SMITH's report. Among them was noted the startling fact that at least 49 per cent. of the entire population of New York city was receiving free medical care and medicines. A number of physicians followed adding equally strong testimony, and showing that most of the great charity clinics and hospitals were literally pauperizing and creating more abuses and distress than they relieved. While this is an old story in New York, and an outrage on progress and rational science, which the profession submit to with stolid indifference, it is strangely spreading to other cities and even small towns of the country. Within a few months over a dozen hospitals and free dispensaries have been established in small suburban cities and villages, with a flourish of names and donors as if they were really charities. The profession have themselves to blame for this sad state of miscalled charities. This discussion only brought out in clearer light an evil, which it is hoped the leaders of the New York medical profession will cure with skill and success. It is a curious commentary on the fads of the profession, that twenty-six of the forty-five papers read were on surgical subjects. Two on alcohol and tobacco, one on expert testimony, one on materia medica, and twelve on abuses of medical charities and allied subjects. This meeting always brings together a large number of country and village practitioners of the better class, and the papers and discussions are always of a high order, and very practical. While the New York medical teachers contribute their full share of papers, the men from outside are equally clear and practically scientific, their contributions are as eagerly followed, and many of them are better contributions to medicine. It is interesting to note that this Association is the only State society with a permanent home in America. The Mott Memorial Hall was a gift of that distinguished surgeon, and includes a fine building, library and museum, with a fund to perpetuate it.

By an arrangement with the trustees the New York State Medical Association came in possession of this property, and through its trustees continue the care and management of the building, and hold its annual meetings and committee meetings in its halls. The building and site are valued at $80,000, and the museum and library are equally valuable. The New York State Medical Association is the permanent trustee and manager of this property, using it for their purposes, and it is open to members as a place to resort while in the city. The library is open to the public, and contains a rare collection of books on medicine, and a very extensive pamphlet and journal literature. This Society has always been in close affiliation with the AMERICAN ASSOCIATION and has done much to redeem the mistakes of some other medical men in this State. The president elect was DOUGLAS AYERS, M.D., of Fort Plain, N. Y., and the secretary, the well-known E. D. FERGUSON, M.D., of Troy, N. Y. This Association is divided up into five district societies which hold quarterly meetings in different parts of the State. These meetings are very popular and largely attended, and are noted both for their social and scientific attractions. The interest which they create extends to the State Association, and is in many respects a model for other State societies.

CORRESPONDENCE.

Ballston Springs, N. Y. as a Resort for Invalids.

HARTFORD, CONN., Oct. 23, 1897.

To the Editor:—In answer to some inquiries, I would say that the famous old watering place of Ballston Springs, New York, is practically an ideal place for nervous and dyspeptic persons who need a change of surroundings, with quiet, and nature's great remedies, mineral waters. Half a century ago this was the most prominent mineral springs resort in America. Saratoga, four miles north, was a mere hamlet. Now Saratoga has become a great center of hotels, sanitariums and springs, and Ballston is a quiet, dreamy suburban village. Down in a valley protected from the high winds, in the dry bracing air of the Adirondack snow belt, free from fogs and sleet storms, it has many attractions as a residence for invalids. To many persons the invalid atmosphere of sanitariums and the unrest and excitement of hotels are depressing and injurious. Whereas the geniality and quietness of a private family is a strong tonic of great value. The springs of Ballston are the same as at Saratoga, being on the same mineral belt, and are mostly soda, magnesia, potassa, iron and lithia waters. Some of them are strong carbonated waters and very agreeable to the taste. I should urge invalids from deranged digestion and nervous debility, to go to Ballston, select some private house as a home, near some of the many springs, and drink freely of the waters. This, with the rest and change, will bring a recovery and full and final restoration in many cases. This advice followed by an invalid physician, resulted in his return home restored after a two months residence. Personally I have seen most excellent results from the use of these waters drunk at the springs regularly every day, and I am convinced many persons supposed to be chronic cases would be restored by such treatment. Beyond this a number of persons who are semi-invalids, would find this an excellent place for the change of scenery and surroundings. The town is a very old one and rich in historic interest, and contains many quiet old homesteads where visitors can find most agreeable places of residence. I believe the waters and the quiet restful atmosphere of Ballston, make it far superior to many foreign springs that are famous resorts, and it will be a pleasure to be of any assistance to any one who would like to spend a short time at this place. T. D. CROTHERS, M.D.

Lepers of New York Turned Loose by the Board of Health.

NEW YORK, Oct. 20, 1897.

To the Editor: -The public be d——! Whether leprosy is contagious or not does not seem to be the question with our New York Board of Health. The point is to escape responsibility, care and trouble. Let the leper go; we are glad to get rid of him on any terms!

It is a lamentable circumstance that such devil-may-carelessness should exist just on the point where it can do the most evil. New York is the most important port of our country. The lepers are foreigners; most of them come from Norway, Sweden, Iceland, South America and the West Indies to New York. Most of the lepers who live in Minnesota and Wisconsin came through New York. Had they remained here instead of going to those far off States, would the New York Board of Health dare to have let them run loose? Horrified public opinion would have compelled their isolation.

There is another question which regards the leper himself rather than the public. What will become of him, left to himself, ejected from one house, finding by deceit a short-lived shelter in another, every man's hand against him? Who will employ him? How will he live? A public charge he must be; if not on the board of health, on the State. I would not answer for his not being stoned or hung to a lamp-post by an angry populace.

Whether the board of health will take the trouble of keeping apart and taking care of the lepers is not a thing in which the City of New York, or the State of New York, alone is interested. All the neighboring States, New Jersey, Pennsylvania, Illinois, etc., are interested in the matter, that is, in the question whether the board of health maintains isolation, or *defies* not only public opinion, but professional opinion; that is the declaration of the most eminent body of leprologists that the world has ever seen assemble; I mean the Conference at Berlin. ALBERT S. ASHMEAD, M.D.

Ship Island Quarantine.

NEW ORLEANS, LA., Oct. 17, 1897.

To the Editor:—In reference to an editorial in the JOURNAL of Oct. 9, 1897, "The Public Health Bill," it seems right to say: This editorial implies that the epidemic of yellow fever now existing in the Gulf States was introduced through the Ship Island Quarantine. Now, I would say that there is no evidence whatever that it was so introduced and much to the contrary. I have not the time now to give the results of the investigations that have been made, but would say that the professional members of the Board of Health of Louisiana have expressed to me decidedly the contrary opinion. All the members of the Mississippi State Board with whom I have spoken, including its secretary and president, have expressed a similar opinion. Dr. Dunn, the member of the Mississippi Board stationed at Ocean Springs, Miss., who took especial pains to investigate the origin of the fever, stated that there is not the slightest reason to believe that the fever in Ocean Springs came in via Ship Island and that everything indicated that it was introduced from another source. Very respectfully,

H. R. CARTER, Surgeon U. S. M.-H. S.

ANSWER.—We have advice to the contrary, and would in reply ask Dr. Carter what form of night patrol, if any, has been in use at the Ship Island Quarantine, and what precautions have been taken to prevent ships' crews from rowing ashore at night?

Rapidly Performed Pyloroplasty.

ROCHESTER, MINN., Oct. 18, 1897.

To the Editor:—My article on "Cicatricial Stenosis and Valve Formation as a Cause of Pyloric Obstruction, with a Report of Five Cases Relieved by Operation," published in the JOURNAL Oct. 16, 1897, contains three cuts of a method of rapidly performing pyloroplasty which add largely to the interest of the publication.

These cuts were furnished me by Dr. A. J. Ochsner of Chicago and represent a method original with him, and not with myself, as would appear. The proofs which I examined did not contain the diagrams and by some oversight their source was not properly acknowledged.

Very truly yours, W. J. MAYO, M.D.

Prizes for Medical Essays.

To the Editor:—What prizes, if any, are now open for competition to the writers of medical essays? Could you inform me what the prizes are, when they are to be awarded and to whom the essays are to be sent? Truly yours, N. O. N.

ANSWER.—"Competition for the Senn Medal," *vide* JOURNAL, July 3, 1897, p. 42; "The Alvarenga Prize," this issue, page 927.

PUBLIC HEALTH.

An Epidemic of Whooping Cough much Attenuated by intercurrent vaccination is reported in the *Gaz. d. Osp.*, of August 3. Sixty-three children were vaccinated and 50 per cent. of those under 4 years were cured completely. In those over 4 years there were six cured, eleven much improved, while thirteen were not affected. Marigo adds that the satisfactory results secured should encourage further trials.

The Question of Serotherapy in the Bubonic Plague has been solved, Metchnikoff reported at the Moscow Congress, but in practice it will be necessary to produce serums far more active than those hitherto in use, and especially stronger in antitoxic power than those employed in British India during the campaign of 1897. Even with the weak serums at his disposal, Yersin succeeded in reducing the mortality from 80 to 49 per cent., and his prophylactic vaccinations were signally successful.

The Value of Mallein as a Test for Glanders is confirmed by Nocard, who states that every animal responding completely to the test (organic and thermic) should be killed and that those who do not respond are not affected by glanders, no matter what symptoms they may present. He recommends inspection by the authorities and licenses for the horses in livery stables, etc., frequently renewed, with disinfection of stables, etc., after a fair or other gathering.

Mortality and Hereditary Syphilis in Children of Prostitutes.—It has been a regulation in Hamburg, for twenty seven years, that every prostitute confined at the public hospital must bring her child to the city physician every month or oftener for examination, until it is a year old. S. Werner publishes a report of the results in the *Woch. f. prak. Derm.*, Vol. 24, Nos. 4 and 5, which is an important contribution to the study of hereditary syphilis. The mortality among the children is high, 63.5 per cent. from syphilitic mothers; 57 per cent. from non syphilitic. Several instructive instances are related of inheritance of post-conception infection, and one of the still disputed *choc en retour*. Tardy symptoms after the first year were seldom noted. Four healthy and five diseased children were born in nineteen cases of simultaneous conception and infection; the rest aborted. Fourteen children inherited syphilis in 31 cases of tertiary disease. The effect of treatment before and during pregnancy is also studied.—*Cbl. f. Chir.*, August 4.

Resolutions of the Illinois State Board of Health.—The secretary reports as follows: "The Board at its meeting (*vide* JOURNAL, October 6, p. 817) adopted a resolution recognizing the diplomas of the Playfair School of Midwifery, 169 South Clark St., and the Chicago Midwife Institute, 233 La Salle Ave., on condition that these institutions comply with the schedule of minimum requirements for schools of midwifery. It was also resolved that after Jan. 1, 1901, no schools of midwifery or medicine will be recognized unless their instruction is in the English language. A resolution was also passed requiring all non-graduate applicants for license to practice medicine and surgery in Illinois, who are required to submit to examination in accordance with the provisions of the Medical Practice Act, to present as evidence of satisfactory preliminary education, either a diploma or certificate of graduation from a high school, evidence of having passed the matriculation examination to a recognized literary or scientific school, or a certificate of successful examination by the faculty of any reputable university or college, or by the State Superintendent of Public Instruction in the following branches: English grammar, arithmetic, elementary physics, United States history, geography and Latin (equivalent to one year in a high school). As a further test of the qualifications of the candidate as a practitioner, each applicant is required to present a certificate signed by a demonstrator of a medical college in good standing with this Board, attesting that the applicant has pursued the study of practical anatomy in said college and has made dissections of the entire cadaver."

Low Death Rate in Brooklyn.—The *Bulletin* of the Department of Health of Brooklyn, October 9, shows for that week the low rate of 14.7 deaths per 1,000. The deaths from all causes were 332 in number, the population being estimated at 1,180,000. There were no deaths registered from variola, measles or scarlet fever. By the first named cause there has been no death for a period of eleven weeks; by measles none for four weeks; by scarlet fever, with one exception, none for nine weeks. Diphtheria and croup have their fluctuations, but no material change from month to month. Typhoid fever mortality is higher than in the former quarter, but about the same as in the year previous. The number of reported cases has been so great as to induce the health commissioner to address a circular to the medical profession, inviting its co-operation in his efforts to seek out the sources of trouble; that circular, bearing date October 4, is as follows: "As typhoid fever is unusually prevalent in the city this fall, unusual efforts to determine, and if possible to abolish, the source or sources of infection, are eminently advisable. You are urgently requested to aid the department in this work by reporting promptly every case of typhoid that comes under your care. Beyond leaving at the house the usual circular of information, it is not our intention to interfere with these cases in any way, as it is not considered that isolation or school exclusion is called for. Our inspectors will be instructed to confine their inquiries to possible sources of infection." Deaths by malarial fevers are rare and for a period of one month six fatal cases only were recorded. The mortality of New York City, for the week ending October 9, was about four points higher per 1,000 than that of Brooklyn for that week. Can it be that the attention of the authorities of the former city has fallen off in regard to the cleaning of streets and the arrest of pasteurized milk purveyors, about which so much has been written during the past few months?

The Paris Sanitary and Biologic Plant.—Dr. E. H. Wilson, bacteriologic expert of the Brooklyn Board of Health, visited Paris last summer and was most hospitably entertained by Dr. Roux. The doctor says that the antitoxin plant is located at Garches, a suburb of Paris, and is about nine miles from that city. It is an auxiliary to the Pasteur Institute and is under the direction of Prof. Roux. "The professor was very courteous and drove me out to Garches, where the entire day was spent by him in showing me the details of the plant. They produce there antitoxin for diphtheria, tetanus and the bubonic (or Chinese) plague. The serum for the plague is sent out to Dr. Yersin in Amoy, where there is a branch of the Pasteur Institute, and his serum is being used with marked success in India. They have 150 horses for diphtheria antitoxin and the care bestowed on these animals and the general management of the plant is well worth observing. Each horse spends the third day in the field. An entry clerk keeps all the data in reference to the injections and the other details of the process. The horses are all in the very best of health and attended with the greatest possible care. All the guinea pigs used in the standardization of the serum and for other purposes are kept at this plant. They have over one thousand guinea pigs there. The personnel of the establishment numbers about 20, and consists of a director, a resident superintendent, 11 stable hands, 2 laboratory hands, 1 laboratory assistant, who is called the inspector; 1 record clerk and 3 women who are employed in bottling antitoxin. The general impression of the whole place convinces one that all such work involving care and health of animals should be done in the country and not attempted in the cities. In regard to municipal disinfection, for that was the next thing I investigated, as a preface I would say that the system used in Paris is in the main similar to that used in Brooklyn before the Board of Estimate cut down the appropriation so as to compel the discontinuance of our plant. It is called the Municipal Service of Disinfection and is under the care of the Prefecture of the Seine. It consists of two corps of men, one for disinfection of the house, and the other for the disinfection of the goods at the stations. They have in the city of Paris four disinfecting stations. The principal station is at 6 Rue des Recollets. The disinfection is done by steam under pressure. The goods are taken there by the collection wagons, which are used for no other purpose, and by men who do not handle disinfected goods. Then the goods are put in ovens on the infected side of the building and subjected for a certain time to a high temperature. They are then removed to the disinfected side by men who never handle infected goods. These two bodies of men have absolutely no communication with each other. After the process of disinfection the goods are delivered in clean wagons prepared for that purpose. Now while this is being done the corps of men at the house disinfects the sick room. This is done by scrubbing the floors, scrubbing the walls in case they are smooth, or in case of frescoed walls by spraying them with an atomizer filled with disinfecting solution. The appropriation for this service in 1896 was about 362,000 francs. Of this amount 353,000 francs were for the general service and 9,000 francs for the disinfection of schools.

Yellow Fever.—Our report for last week closed with dispatches of the 19th, announcing 56 new cases and 4 deaths at New Orleans. At other cities, on the same date, the following was the record: Mobile, 5 new cases, with 2 near Mobile; Edwards, 4 cases; Clinton, 4 cases, Scranton, 4 cases; Pascagoula, 1 case, while at Montgomery, Ala., State Health Officer Anders reported that there were 4 known cases there, and probably more. Biloxi reported 21 new cases and 1 death, and at Waveland, Miss., 2 of the 3 "suspicious" cases were declared yellow fever, while McHenry reported 1 new case. October 20, dispatches were as follows: Montgomery, Ala., 1 death and 5 new cases; New Orleans, 53 new cases and 6 deaths; Edwards, 4 new cases; Queen's Hill neighborhood, 3 new cases; Cayuga, 5 new cases. October 21.—New Orleans, 43 new cases and 2 deaths; Montgomery, Ala., 4 new cases; Mobile, 1 new cases and 3 deaths; Wheelerville, 2 cases; Flomaton, 2 new cases; Clinton, Miss., 4 new cases; Nittayuma, 2 new cases; Edwards, 5 new cases; Bay St. Louis, 7 new cases with 1 death, and Cayuga, 5 new cases. October 22.—New Orleans, 50 new cases, 5 deaths; Mobile, 10 new cases, 5 of which were taken from the Italian bark *Livomus*, also 2 deaths; Memphis, 1 "suspicious" case; Cayuga, 1 new case; Bay St. Louis, 1 new case; Edwards, 4 new cases. October 23.—As a result of investigations at Selma, Ala., 7 cases were declared yellow fever in that city; Montgomery reported 13 new cases and 1 death; Mobile, 6 new cases; New Orleans, 49 new cases and 7 deaths; Memphis, the "suspicious" case declared to be yellow fever; Bay St. Louis, 7 new cases; Clinton, 2 new cases; Cayuga, 1 new case; Nittayuma, 6 new cases; Edwards, 2 new cases. The State Board of Health on this date quarantined the State of Mississippi against Alabama. October 24.—New Orleans, 31 new cases and 3 deaths; Selma, Ala., 3 new cases and one death. October 25.—The Board of Health of Memphis. Tenn., reported 3 new cases and 2 deaths; Mobile, Ala., 7 new cases and 1 death; Montgomery, 4 new cases and 1 death; Raymond, Miss., 1 new case; Edwards, 1 new case; Bay St. Louis, 6 new cases and 1 death; Biloxi, 1 death; New Orleans, 57 new cases and 11 deaths, the largest number of deaths for any single day. Heavy frosts are reported from Atlanta, which makes the outlook there encouraging. Dispatches of the 26th report 50 new cases at New Orleans, with 5 deaths; Montgomery, 10 new cases and 1 death; Selma, 1 death; Mobile, 3 new cases; Baton Rouge, 2 cases; Memphis, 7 new cases; Biloxi, 14 new cases: McHenry, 1 new case and 1 death: Scranton, 10 new cases, and Bay St. Louis, 1 death. Yellow fever is also declared to exist at New Albany, Miss.

Yellow Fever Immunes.—The Florida State Board of Health has issued the following circular:

Pensacola, Fla., Sept. 27, 1897.

To the Citizens of Florida:—It has been computed from statistics upon the subject that only one person in nine thousand may suffer from a second attack of yellow fever. Therefore one seizure may be considered as determining for all practical purposes of public safety an immunity to the disease. In 1893 the State Board of Health of Florida adopted a method for the benefit of the many thus protected, by perfecting a system of "Immunity Credentials" by a certificate of immunity to yellow fever in the form of a card of convenient pocketbook size, which attests, under the seal of the State Board of Health and the signature of the State Health Officer, that the bearer had yellow fever, with place, date and name of attending physician, together with an accurate personal description and the autograph of the bearer. These cards are numbered and registered in the office of the Board at Jacksonville. They do not, however, exempt the baggage of the holder from disinfection should he or she have baggage from a yellow fever infected district.

As there are now many persons in Florida who, having had an attack of yellow fever, can be said to be "immune" and protected from subsequent seizure, it is desired to invite the attention of these yellow fever "immunes" to the great personal benefit which the possession of the card herein described confers, as giving freedom in travel in yellow fever districts (without baggage, of course, or baggage which has been disinfected). The identification of the party holding such card can always be established by comparing his or her signature and by telegraphic or other reference to the office of the Board at Jacksonville. This subject has been taken up with the boards of health of the Southern Gulf States, and already very encouraging replies promising co operation have been received.

There is no charge for these "immunity cards," nor for any health certificates issued by the State Board of Health of Florida. The proof of having experienced an attack of yellow fever must be substantiated by indisputable evidence before an "immunity card" will be issued.

JOSEPH Y. PORTER, M.D.,
State Health Officer of Florida.

YELLOW FEVER IMMUNITY CARD.

This certifies that . . . .
a native of . . . .
and resident of. . . . . .experienced an
attack of yellow fever at. . . . .
in 18 . . Attending Physician . . . . . .
No . . . .
State Health Officer of Florida.

This card does not exempt baggage and personal effects from disinfection.

NECROLOGY.

W. D. BRATTON, M.D., Passed Assistant Surgeon, United States Marine-Hospital Service, died at Sabine Pass, Texas, October 2. A circular from the Marine Hospital gives the following: During the present yellow fever epidemic in the South, Passed Assistant Surgeon Bratton, although an invalid and therefore on waiting orders, promptly volunteered his services to meet the emergency, and the tender was accepted. He was ordered to Sabine Pass where he arrived September 28. On Oct. 1 he had been superintending the disinfection of a vessel, and returning to the ship to reinspect it, he fell through a ventilating hole, striking his head upon an iron knee, producing concussion of the brain. He remained undiscovered for several hours and when found was unconscious and remained so until death occurred eighteen hours after the unfortunate accident. William DuBose Bratton was born in Fairfield County, South Carolina, June 23, 1860, the son of Gen. John Bratton of Winnsboro in that State. His early education was acquired in Mt. Zion School, Winnsboro, and at Abbeville, S. C. In 1874 he was matriculated at the Carolina Military Institute at Charlotte, N. C., remaining two years, and then entered the University of the South at Sewanee, Tenn., where he received the degree of B.S. in 1880 after a three years' course. He began the study of medicine and was graduated at the Medical College of South Carolina March 1, 1881, and for the year following was house surgeon at the Charleston City Hospital. He was commissioned as assistant surgeon April 1, 1885, and assigned to duty at New York. His subsequent stations while in that grade were San Francisco, Cal., as medical officer of revenue cutter *Corwin* for service in Alaskan waters and then for temporary duty at Port Townsend, Wash. He was commissioned a passed assistant surgeon April 2, 1888, and again assigned to duty as medical officer on the revenue cutter *Bear* for service in Alaskan waters. In May, 1889, he was ordered to duty in command of the service at Portland, Oregon, where he remained two years and was then assigned to duty at Chicago, Ill. In 1893 he was placed in command of the service at Buffalo, N. Y., where he remained till Jan. 9, 1894. In the fall of 1893 he first became aware that he had tuberculosis and he was sent to Wilmington, N. C., for its favorable climate, where he remained several months, meanwhile doing temporary service at Delaware Breakwater Quarantine, but later he was placed on "waiting orders" (Jan. 1, 1895), taking up his residence in Arizona and finally at Albuquerque, N. M., to obtain the advantages of the southwestern arid region. After a two years' residence there he reported, in March, 1897, his gradual return to health, which justified him in asking for an early restoration to active duty, but further delay was advised in order that he might have the benefit of a longer residence and, if possible, a permanent cure. Passed Assistant Surgeon Bratton, during the period of "waiting orders," became much interested in the climatic treatment of consumptives and wrote several reports on the arid region of the Southwest as the best locality for such work, recommending the establishment of a sanitarium in that section for the treatment of patients suffering from the disease. His literary and scientific attainments were of a high order and his studious habits and keen faculties enabled him to maintain in the service a reputation for unusual professional knowledge and skill in practice. Officially, devotion to duty was always a paramount consideration with him and his conscientiousness in respect thereto was a marked characteristic of his work. Personally, he was of modest and reserved manner, yet frank and manly in his demeanor and actuated by a high sense of honor in all relations with his associates. He hated subterfuge and despised an ingrate. He was an honest man and a gentleman.

JAMES P. DALY, M.D., Bellevue, N. Y., 1886, a candidate for Coroner in the borough of the Bronx, New York City, died at his home during the early morning of October 15. Apoplexy, the cause of his death, was thought to have been superinduced by excessive campaign work. He was of delicate health and had been a school inspector for six years.

GEORGE RICHARD SMITH, M.D., died at the Plaza Hotel, New York City, October 17. His remains were interred in Oneida, N. Y.

WM. H. FORD, M.D., University of Pennsylvania, 1863, President of the Philadelphia Board of Health, died suddenly at his summer home in Belmar, N. J., October 19, aged 58 years. He was a member of the board for twenty-seven years, and was a writer on sanitation and hygiene of considerable repute.

JOHN A. RAUB, M.D., University of Pennsylvania, 1862, at one time president of the Northampton County Medical Society, died in Philadelphia September 29, aged 61 years.

JARRARD K. SMITH, M.D., Government physician at Koloa, Sandwich Islands, was shot down in his doorway September 24 by a native whose mother and sister had been ordered as lepers to Molokai. There are some reasons for believing that he was identical with Dr. Jared Knapp Smith, College of Physicians and Surgeons, New York City, class of '76, as he was born on the island of Kaui and received his medical training in New York City.

VINCENT ZOLNOWSKI, M.D., University of Vermont, 1883, of New York City, died at his summer home, Lake Ronkonkoma, L. I., October 21. A son of the same name, also a physician, survives him.

R. A. EVERETT, M.D., Hillsdale, Mich., October 20, aged 58 years, one of the founders of and at one time president of the Southern Michigan Medical Society.——William H. Veatch, M.D., Carthage, Ill., October 10, aged 66 years.——Joseph C. Wheaton, M.D., Jefferson 1883, of Millville, N. J., died there October 13.——Girard R. Ricketts, M.D., Western Reserve Medical College, Cleveland, Ohio, 1855, died at his home in Proctorville, Ohio, September 20. Three sons, all physicians of Cincinnati, Ohio, survive him. He was born in Virginia in 1829.

BOOK NOTICES.

The Practice of Surgery.—A Treatise on Surgery for the use of Practitioners and Students by HENRY R. WHARTON, M.D., and R. FARQUHAR CURTIS, M.D., profusely illustrated. Philadelphia: J. B. Lippincott Company, 1897. Pages 1240.

The book has 38 chapters, which fairly cover the extensive field of surgery and surgical pathology.

Naturally there must be difference of opinion as to the relative space to be accorded each topic. But taking it as a whole it is perhaps as fairly divided as can be. Due consideration has been given to the wants of the student and practitioner, and in many respects the work is a praiseworthy one.

A great many of the illustrations we notice are from Agnew's great work on surgery by the same publisher, which doubtless accounts for their rather free introduction. The topics seem to be brought fairly down to date, and include the essentials of the practice of surgery.

Naturally in any work not encyclopedic there must be some omissions. we note for example in the operative treatment of varicose veins the Schede method is not referred to, and on the next page the presentation of the subject of "cirsoid aneurism," is entirely inadequate; but we have seen, so far as we have examined the book, no positive errors of statement, and the omissions are not of a character to make the loss deeply felt by those who depend upon it for information. We commend the book as the latest and one of the very best text books on surgery at this date.

A Manual of Medical Jurisprudence. By ALFRED SWAIN TAYLOR, M.D., F.R.S. Revised and edited by THOMAS STEPHENSON. London. Twelfth American edition. Edited with citations and additions from twelfth English edition by CLARK BELL, Esq., LL.D. Pages 832. New York and Philadelphia. Lea Brothers & Company. 1897.

It may well be conceded that the advent of an energetic editor like Mr. Clark Bell would result in vast additions to the book and one is not disappointed in so considering. To most of us the "Taylor Medical Jurisprudence" comes like an old friend to whom we turn for counsel and support in case of need.

The present edition has preserved all the valuable features which made the old Taylor so popular and at the same time has introduced much of modern matter.

The chapter on "Medico Legal Surgery" is a distinctly new feature of this edition and for the first time "railway" surgery figures as a recognized specialty in legal medicine.

Report of the Commissioner of Education for the Year 1895-96 Vol. 1, containing Part 1. Washington Government Printing Office. 1897.

The volume is a valuable addition to educational history. The introduction by the commissioner, William P Harris, PH.D., LL.D., contains statistic tables comparative of educational conditions in the United States since 1870, from which it would appear that while the population has nearly doubled, educational advantages have kept pace. The percentage of population enrolled in schools and the per capita expenditure are both greater; likewise the average time attended by each has been prolonged.

The remainder of the volume is taken up with various educational matter pertaining to the United States and countries of Europe.

SOCIETY NEWS.

The International Lepra Conference at Berlin was auspiciously inaugurated October 11 with 150 members, including forty four delegates from twenty seven governments and scientific societies, Virchow presiding. Carrasquilla's report is awaited with interest as his serum is being tested in France, Italy, Japan, India, Mexico, etc. The Paris committee consisting of Fournier, Besnier, Roux and Hallopeau, reported to the Académie de Méd., September 28, that they find the serum ineffectual, and that C.'s announcements of improvement and cure were premature. The subsidence of the disease in a few cases after treatment can only be ascribed to the intermissions characteristic of the affection. Buzzi of Berlin, on the other hand, is most favorably impressed with the results in his one case, and the South American papers state that delegates sent to Bogota from Mexico and Costa Rica, reported in favor of the treatment on their return.

The Association of Medical Officers of the Maryland National Guard has been organized in Baltimore. All the active medical officers of the Guard are members. The officers for the current year are: Major George H. Rohé, Surgeon 5th Reg. Veteran Corps, *president*, Brig. General Ridgley B. Warfield, Surg. Genl. Med. Nat Guard, vice president; Captain J. B. Schwatka, Asst. Surg. 4th Regiment, secretary treasurer. The Executive Committee consists, in addition to the above mentioned officers, of Col. Robert W. Johnson, Med. Director, 1st Brigade; Maj. J. D. Norris, Surgeon 4th Regiment; Capt. I. R Trimble, Assist. Surgeon 5th Regiment, and Lieut. Sidney O. Heiskell, Surgeon Maryland Naval Reserves. The Association has been formed in order to promote the efficiency of the medical service of the Maryland National Guard. The organization and its objects have the approval of the Governor and the military authorities of the State.

MISCELLANY.

The Use of Glass Weights has been authorized by the Swiss government, made by the Schmid patent (Schmid of Bulach).

To Succeed Dr. Bates. The President has appointed Medical Director W. K. Van Reypen to be Surgeon General of the Navy to succeed Surgeon General Bates, deceased. The duties of the office are quite familiar to Dr. Van Reypen, as he acted in the capacity for some time, and was also regularly detailed as Assistant in the Bureau of Medicine and Surgery.

The Benjamin Rush Monument.—At the recent meeting of the New York State Medical Association, the pledge made in the name of the Association, to give $2,000 to the Rush monument fund was redeemed, and $2,000 set aside for that purpose.

Office Removal.— The office of the Secretary of the Association of Military Surgeons of the United States has been removed from Columbus, Ohio, to Fort Crook, Neb., because of a recent War Department order transferring James E. Pilcher, M.D., the Secretary, to that point.

Proof of Death Demanded.— An insurance journal reports that a certain Dr W A Dunn of Elkhart, Ind., was insured to the amount of $20,000 He is alleged to have died in Naples, Italy. His body was brought home in a sealed casket and interred, the casket not having been opened. Companies refuse to pay on the ground that there is no evidence that he is dead. They will resist until such evidence is presented.

Hydrophobic Paralysis. Professor Calabrese describes in *Rif. M I*, p. 172 an unusual case of hydrophobic paralysis in a young woman, a hysteric, bitten on the lips, which combined all the bulbar and dorsolumbar symptoms. No antirabic treatment was attempted. The temperature fell from 42 to 37.7 degrees C. twenty-four hours before death. The disease lasted fourteen days. Some have ascribed the transient paralysis observed during antirabic treatment occasionally, to the treatment (*vide* JOURNAL, pp. 201 and 818), but facts like the above tend to prove that it is merely an attenuated form of the disease.

An Inflammable Cosmetic.—Of all the life-destroying devices employed by women a certain petroleum hair wash stands in the front rank. The *Insurance Observer*, London, mentions an accident caused by the ignition of this mixture. It is also known by the names "Antiseptique Liquide," "Dry Shampoo," "Pétrole," "Le Fin de Siècle," etc. It consists chiefly of petroleum spirits which give off inflammable vapors at ordinary temperatures.

Colds as a Factor in the Etiology of Disease.—E. Fischl reports some interesting experiments exposing rabbits to attenuated pneumococcus infection after allowing them to get chilled, the results of which show that getting chilled is a predisposing element of great importance in the etiology of disease. Further research showed that the bactericidal power of the blood serum is not altered, but that the phagocytosis is seriously affected.—*Wien. klin. Woch.*, August 26.

The Alvarenga Prize.—The College of Physicians of Philadelphia announces that the next award of the Alvarenga Prize, being the income for one year of the bequest of the late Senor Alvarenga and amounting to about $180, will be made on July 14, 1898, provided that an essay deemed by the Committee of Award to be worthy of the prize shall have been offered. Essays intended for competition may be upon any subject in medicine, but can not have been published, and must be received by the secretary of the College on or before May 1, 1898. Each essay must be sent without signature, but must be plainly marked with a motto and be accompanied by a sealed envelope having on its outside the motto of the paper and within the name and address of the author. It is a condition of competition that the successful essay or a copy of it shall remain in possession of the College; other essays will be returned upon application within three months after the award.

A Defective Ambulance Service.—The JOURNAL, which has heretofore criticised the defects of the ambulance service in Chicago, and especially the want of proper medical attendance at the police stations and in cases of emergency, is gratified to learn that the Health Commissioner, Dr. Arthur R. Reynolds, has recently made a practical test of the service which discloses a condition of affairs fully justifying the JOURNAL'S strictures. The city provides six ambulances at police stations to cover 180 square miles of territory, but none of these is furnished with a medical man; occasionally a physician in the vicinity of a police station or a senior medical student volunteers his services. Dr. Reynolds selected four of these ambulances, assigned a surgeon to each and equipped each vehicle with the necessary appliances, etc., for furnishing "first relief." In an aggregate of 181 days of service these gentlemen answered 429 calls, traveling an aggregate of 2,441 miles, and gave "first aid" and then transferred 277 cases to hospitals and 81 to their homes by ambulance, the remainder being treated either where found or at the stations and then discharged. In addition to this service 51 cases among prisoners at the stations were also treated. Among the 429 ambulance cases were 24 injuries from street-car accidents, 13 from bicycles, 6 from railroads, 52 from falls from scaffolds, etc., 16 gunshot and 20 stab wounds. The injuries embraced simple and compound fractures, dislocations, contused, incised and lacerated wounds, sprains, bruises, etc. Among the remaining cases were resuscitation from drowning, bites by alleged rabid dogs, poisoning, burns, scalds, acute appendicitis, typhoid fever, rheumatism, delirium, insanity, attempted suicide, alcoholism, epilepsy and heat prostration. Dr. Reynolds says: "Some lives were undoubtedly saved by this service, as well as much suffering, through prompt treatment, correct diagnosis, arrest of hemorrhage, administration of antidotes, etc. A correct diagnosis, as, for example, of a person found unconscious, which condition may be due to a fracture of the skull, concussion of the brain, alcoholism or other cause, is of the first importance, as recent unfortunate occurrences demonstrate. Concerning the ambulances it is noted that none of these vehicles is of the modern style and all lack in important requirements. They seem to have been kept in as cleanly condition as the resources of the stations permitted; but an ambulance for the transport of the varied class of cases with which the police have to deal should be of the most approved type, strong but light, easy riding, rubber-tired and capable of being kept surgically clean, lest an unfortunate contract some other disease from a previous occupancy or have blood poisoning added to the dangers of his wound or injury." This object lesson should serve a useful purpose in arousing the city fathers to a condition of affairs which is a disgrace to the community, and should result in securing an adequate appropriation for the establishment of a creditable, humane and efficient provision under the supervision of the Health Department for the relief of emergency cases of sickness and injury.

Societies.

The Southern Missouri Medical Association will hold its twenty first semi-annual session at Malden, Mo., November 2, 3 and 4.

The following meetings are noted:

Connecticut.—Hartford County Medical Association, Hartford, October 20.

Illinois.—Chicago Medical Society, October 20: DeWitt County Medical Society, Decatur, October 12. District Medical Society of Central Illinois, Taylorville, October 26. Iowa and Illinois Central District Medical Association, Rock Island, October 14. Illinois Military Tract Medical Association, Galesburg, October 21. Morgan County Medical Society, Jacksonville, October 14.

Iowa.—Cedarville Medical Association, Independence, October 13.

Kentucky.—Clark County Medical Society, Louisville, October 12.

Michigan.—Detroit Academy of Medicine, October 12. Wayne County Medical Society, Belleville, October 11.

Missouri.—Jackson County Medical Society, Kansas City, October 14.

New Hampshire.—Strafford District Medical Society, Dover, October 13.

New York.—Central New York Medical Association, Buffalo, October 19. Niagara District Medical Association, Niagara Falls, October 13. Northern New York Medical Association, Ogdensburg, October 12. Oneida County Medical Society, Rome, October 12.

North Carolina.—The Medical Society of Mecklenburg was organized October 12.

Ohio.—Eastern Ohio Medical Association, Bellaire, October 20.

Pennsylvania.—Lebanon County Medical Society, Lebanon, October 12.

Vermont.—The eighty-fourth annual meeting of the Vermont State Medical Society, St. Albans, October 14.

Virginia.—Richmond Academy of Medicine and Surgery, October 12.

Washington.

HEALTH OF THE CITY.—Report of Health Officer Woodward, for the week ended October 16, shows the total number of deaths to have been 89, of which 49 were white and 40 were colored. There were 13 new cases of diphtheria and 12 of scarlet fever reported.

EPISCOPAL EYE AND EAR HOSPITAL.—At the semi annual meeting of the Board of Governors recently held, the report showed that there had been 1,132 visits to the eye department; 180 visits to the ear department; 609 to the throat department. While the total number of patients treated was [illegible], and 63 operations were performed. The me[illegible] have decided to give lectures to the nurses and [illegible] to a limited number of medical students. The [illegible] or showed, receipts, $3,056.22; disbursed, $3,461.13 for furnishing and maintenance of the hospital to date. Mrs. Mary M. Carter has donated $5,000 to endow a bed in memory of her parents.

Dairyman Fined.—W. V. Hoff was fined $20 in the police court for selling milk after license had been refused. The Health Office had declined the license because the place of business did not conform with the sanitary regulations of the department.

Medical Society.—At the meeting of the Medical Society held on October 20, S. S. Adams, M.D., presented a plan for the establishment of a milk laboratory and depot in this city. The subject was discussed fully, and a committee appointed to report on the same. Dr. Glazebrook presented a number of interesting pathologic specimens, illustrating the advantages of the Kaserling fluid as a preserving agent.

Denver.

The Medical Department of the University of Denver has inaugurated many changes. The seventeenth opening exercises were held October 5, one month later than in previous years. The term will close one month later. This was done with a view of giving both teachers and students the benefit of recreation and recuperation during the best portion of the year, and also in order not to subject the students to the hardships of working in the dissecting room during the warm days of the season. The antiquated method of dissecting at night was done away with forever. All the work in the anatomic laboratory is henceforth to be done by the light of the sun. While speaking of the Denver University, it is most appropriate to record the death of Dr. John Evans, the second Governor of the Territory of Colorado, which has occurred recently. In him the medical department has lost one of its staunchest friends, for every step in the earliest history of the college was taken under the guidance of the powerful intellect and indomitable will of this master mind.

The first fall meeting of the Denver and Arapahoe County Medical Society was held in the Brown Palace Hotel October 12. Dr. Waxham read a paper on the "Identity of Membranous Croup and Diphtheria." He cited many cases in which the membrane alone appeared in the larynx, yet the bacteriologic examination showed the cases to be diphtheria. Dr. Henry Sewall, Secretary of the State Board of Health, spoke of the difficulty encountered in quarantining such cases. In small towns everything is termed membranous croup, and the children from such families are allowed to attend the public schools. Dr. Levy spoke of two cases which he intubated, one of which had no membrane at all. Both died, and the cultures gave positive results. Dr. G. M. Black read a paper on "Simple Pterygium Operation" and presented a new instrument provided for this purpose. The instrument is a double blade, right-angled and pointed. Dr. Bane in discussing the instrument said he finds it not only useful in pterygium, but also in removing cysts and small growths from the eyeball. Dr. A. C. Godfrey reported a cases of abnormal position of the vermiform appendix in a boy 11 years old, who was suffering from curvature of the spine and frequent attacks of colic. He ate some green apples and had at first all the symptoms of cholera morbus, and later developed those of obstruction of the bowels with tumor palpable in left inguinal region. The autopsy showed the vermiform appendix to be enormously swollen, full of pus, containing several enteroliths and extending across the pelvis, pressing on the sigmoid flexure to such an extent as to produce obstruction. Dr. Axtell spoke of the various positions of the appendix which he had found in a large series of postmortem cases, and he called attention to recent report of three cases of left-sided appendicitis.

The Clinical and Pathological Society held its annual and first meeting of the season October 15. This society is "limited"; it confines its membership to the number of forty, and the roll is always complete. It enjoys the rare distinction of having a full attendance at each meeting, and during the four years of its existence never had a dull meeting. The reason of this signal success is said to be due to the fact that they do not tolerate set papers. Each member reports impromptu interesting cases from actual practice. At the last meeting Dr. Leonard Freeman reported a case in which he operated for inguinal hernia and retained testicle. He removed the testicle and found another one in hiding. The microscopic examination of the first, however, showed it to be an undeveloped kidney. Dr. J. N. Hall presented a patient in whom the flouroscope showed beautifully the transposition of the abdominal and thoracic viscera. Dr. Axtell reported a case of undoubted typhoid fever in which both Widal's and diazo tests were repeatedly made with negative results. Perhaps the most important factor which makes this society the dream of many candidates is the fact that the end of the scientific program does not mean adjournment. The society meets once a month in the office of one of its members, and each host vies with the preceding in the point of hospitality. The annual election of officers resulted as follows: C. K. Fleming, M.D., president; M. G. Black, M. D., first vice-president; Alfred Mann, M.D., second vice-president; J. M. Walker, M.D., secretary, and Leonard Freeman, M.D., treasurer.

Some prominent members of the profession are taking considerable interest in the crematory to be shortly erected by the Denver Cremation Society. Among the initiators are Drs. Axtell, Woodall, Mann and Minnie Love.

CHANGE OF ADDRESS.

Babbitt, W. H., from Raleigh, N. C., to Marion, Ind.
Behrens, B. M., from Benson to 9 E. 25th St., Minneapolis, Minn.
Culver, D. M., from 410 Virginia Ave. to 743 Fletcher Ave., Indianapolis, Ind.
Collins, R. G., from 5139 Wabash Ave. to 5059 State St., Chicago.
Derwent, A. E., from Elma to Lamoni, Iowa.
Dall, S., from 465 Milwaukee Ave. to 667 Oakley Ave., Chicago.
Davis, C. E., from Woodward, O. T., to 225 28th St., Chicago.
Eichberg, L. E., from 332 W. 85th St. to 211 E. 62d St., New York, N. Y.
Hughes, C. U., from Big Run to Eleanor, Pa.
McBride, M. A., from Senior to Yorktown, Texas.
Pilcher, James E., from Columbus, Ohio, to Fort Crook, Neb.
Ragsdale, J. E., from Chapel Hill to Marshall, Mo.
Rathbone, F. W., from Tonganoxi, Kan., to 1015 Prospect Ave., Kansas City, Mo.
Sabin, T. H., from Yuma to Mesa, Ariz.
Schultz, R. C., from 108 E. 54th St. to 305 W. 46th St., New York, N. Y.
Wallace, J. S., from St. Louis to Brunswick, Mo.

THE PUBLIC SERVICE.

Army Changes. Official List of Changes in the Stations and duties of officers serving in the Medical Department, U. S. Army, from October 9 to 15, 1897.

Capt. Peter R. Egan, Asst. Surgeon U. S. A., is granted leave of absence for six months.

Capt. Ashton B. Heyl, Asst. Surgeon (Ft. Riley, Kan.), leave of absence granted is extended two months.

First Lieut. James S. Wilson, Asst. Surgeon (Camp Eagle Pass, Texas), is granted leave of absence for one month.

Capt. W. E. Purviance, Asst. Surgeon (Ft. Columbus, N. Y.), is granted leave of absence for one month.

First Lieut. Guy C. M. Godfrey, Asst. Surgeon U. S. A., is relieved from further duty at Ft. Yellowstone, Wyo., and is ordered to Ft. Yates, N. D., for temporary duty.

Capt. J. D. Poindexter, Asst. Surgeon U. S. A., now on temporary duty in New York City, is ordered to Ft. Hamilton, N. Y., for duty, when relieved from present duty by Capt. William C. Gorgas, Asst. Surgeon U. S. A.

Capt. Norton Strong, Asst. Surgeon U. S. A., upon being relieved from duty as attending surgeon and examiner of recruits at Chicago, Ill., to await orders in that city for the convenience of the Government.

The Journal of the
American Medical Association

VOL. XXIX. CHICAGO, ILL., NOVEMBER 6, 1897. No. 19

ADDRESS.

CHAIRMAN'S ADDRESS.

Presented to the Section on Obstetrics and Diseases of Women, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, June 1-4, 1897.

BY MILO BUEL WARD, A.M., M.D.
KANSAS CITY, MO.

This semi-centennial meeting of the ASSOCIATION is without doubt the most important epoch in its history and forcibly reminds each member of the fact that whatever doctrines may at this time be presented, they will be taken as rules and guides until future events shall have proved them false.

That the teachings to be promulgated during this session of our Section will tend to make this occasion most memorable there can be no doubt. The universally recognized reputations of the authors, and the titles of their papers, make it certain that there will not be any lack of interest in our Section work.

If it be true, and we claim it is, that the happiness and usefulness of the present generation and the perpetuity of vigorous future generations depend upon healthy mothers more than all other elements, then certainly it must be important to give our best thought and labor along the line of greater attainments in preventing diseases peculiar to them and the cure of those suffering from the numerous ailments so common to the female sex.

On this auspicious occasion it seems fitting to occupy a brief moment in reviewing some of the work which has been accomplished during the last half-century by way of a more accurate comprehension of the etiology, pathology and treatment of diseases of women by our American profession, largely in connection with the history of the AMERICAN MEDICAL ASSOCIATION. To do more than to refer to some of the prominent members of the profession and the work they have accomplished is quite out of the question in the time allotted. This résumé must therefore be disjointed and probably disappointing to those who would wish a longer and more exhaustive dissertation.

The organization of the AMERICAN MEDICAL ASSOCIATION occurred at a most propitious time. As great men are always to be found for great emergencies, so this organization was launched just at the beginning of the great awakening of the members of our profession to the possibilities of more extensive fields of usefulness.

In 1847 the very common, and we may say almost simple, operation of ovariotomy had been done less than forty times in America and the mortality, the result of these operations, was over 50 per cent.

The first recorded paper on fibroid tumors of the uterus presented to this ASSOCIATION was read by Dr. W. L. Atlee in 1853. Nothing definite regarding the surgical treatment of these growths was recommended, but the value of ergot was highly commended by the author. The records of the progress of gynecology in America show fully as much advancement as those of the older countries, but nothing of special merit is recorded on these subjects until fully a half-century after McDowell's first ovariotomy.

The inventive genius and consummate skill of the father of American gynecology, Dr. J. Marion Sims, began to be recognized by the profession in the early days of this ASSOCIATION'S history, and the wondrous results of the work performed of this great and good man will continue to bless womankind to the end of the world.

Following closely in his footsteps came Dr. Thomas Addis Emmett, whose teachings and operative skill have tended to enrich the science of gynecology second only to Sims, and he still lives to give us wise counsel and valuable assistance in relieving suffering women. Sims and Emmett may truly be styled the pioneers of American gynecology. The great work accomplished by these two specialists entitles them to the highest encomiums possible to be bestowed by the profession. Imbued with the impetus given by Dr. Sims to gynecology, this great specialty was promptly and enthusiastically taken up by Drs. Emmett, H. R. Stover, Nathan Bozemann, E. R. Peaslee, T. Gaillard Thomas, James P. White, W. H. Byford, Robert Battey and scores of others of whose records the profession has just cause to be proud. Dr. T. Addis Emmett's contributions regarding the subject of laceration of the cervix uteri, the etiology of the affection, its symptoms, the effects on the constitution and the operation for its relief are too universally known to require special mention in this connection. Dr. Peaslee, in 1854, contributed a paper on the treatment of septicemia following ovariotomy, in which he recommended the introduction of a tube into the peritoneal cavity, through which the serous sac was irrigated. Time has proved the wisdom of this method of treatment for this grave condition.

In 1856 Dr. J. P. White of Buffalo reported the successful reduction by taxis of an inverted uterus of eight days' standing. He was the first successful operator in this country to reduce a chronic inverted uterus.

In 1868 Dr. Emmett reported that he had retained partial reposition of the uterus by closing the os externum with silver sutures.

Prior to 1862 but one case of pelvic hematocele had been published. That year three essays on the subject were written, respectively, by John Byrne of Brooklyn, Fordyce Barker and E. Noeggerath of New York.

Dr. Shupper of New Orleans gave the profession, in 1866, an exhaustive treatise on vesico-vaginal fistula.

Dr. Theophilus Parvin operated in [illegible] for [illegible]o-vaginal fistula by turning the displa[illegible] of the ureter into the bladder [illegible] vaginal opening. The operation was successful and original with Dr. Parvin.

The removal of a small ovarian cyst through the cul-de-sac of Douglas was first done by Dr. T. G. Thomas, in 1870.

Dr. Robert Battey of Georgia reported in 1870 a case of extirpation of the ovaries for the relief of dysmenorrhea, the result of which was satisfactory. His name has been made immortal through his acumen in selecting suitable cases and performing what he termed normal ovariotomy.

In 1873 Dr. John Ball of Brooklyn recommended the rapid dilatation of the cervix uteri for constrictures and irregularities of the canal from flexions and versions. Dr. William Goodell of Philadelphia invented a valuable instrument for uterine dilatation and successfully performed a great number of these operations.

One of the greatest advancements in modern gynecology was Dr. Emmett's contribution, in 1874, on the pathology and treatment of diseases of the neck of the uterus.

In 1874 Dr. Sims contributed a valuable paper on the enucleation of intra-uterine fibroids. The same year Dr. Byford of Chicago read a paper on the treatment of uterine fibroids by ergot. Dr. Byford was the first to advocate the use of this drug in very large doses to cause expulsion in addition to atrophy.

In 1874 Dr. Alexander Skene performed successfully to both mother and child, the operation of laparo-elytrotomy. The operation has been done only a few times, with a mortality of about 50 per cent.

Dr. Fordyce Barker of New York, and Dr. H. R. Stover of Boston, were the first American surgeons to call the attention of the profession to the causative relations of uterine and ovarian disease to mental disturbances in women. The former published an article upon this subject in 1872, and the latter a monograph upon the same subject in 1871.

Dr. George J. Engelmann, in 1877, gave the profession a collection of facts concerning hysteroneurosis of the brain, pharynx, larynx, eye, stomach, intestines, bronchi and joints of severe and misleading character, frequently produced by non-development of the uterus or ovaries, or both, or peri-uterine disease.

In 1882 Dr. Christian Fenger of Chicago recorded the first successful operation of kolpohysterectomy for uterine cancer, and at the same time advocated the operation as a justifiable one.

It is claimed that Dr. Charles K. Briddon performed the first celiotomy in 1883, after rupture of the fetal sac in tubal pregnancy.

Dr. Matthew D. Mann was the first to publish a successful operation performed in February, 1883, in which he removed a small subperitoneal fibroid tumor of the uterus through the anterior wall of the vagina.

Dr. Burnham was the first American gynecologist to perform successfully supravaginal hysterectomy. This was in 1853. Dr. Stover and Dr. Kimball were among the first to *boldly operate for large fibroids of* the uterus.

In 1884 Dr. R. S. Sutton did the first celiotomy for pelvic abscess.

Dr. T. G. Thomas performed the first systematic vaginal ovariotomy in February, 1870. Dr. Robert Battey performed the operation first in 1874, and in 1877 successful cases were reported by Drs. Gilmore of Mobile, Clifton E. Wing of Boston and William Goodell of Philadelphia.

To Dr. Robert Newman of New York is given the credit of being the veteran advocate in America of the electrolytic treatment of fibroids of the uterus, thirty years ago.

The first journal devoted to obstetrics and gynecology appeared in 1868, edited by Dr. B. F. Dawson. The specialty of gynecology was not recognized exclusively by any medical journal until, 1869, when the *Journal of the Gynecological Society of Boston* was published and edited by Drs. H. R. Storer, G. H. Bixby and W. Lewis.

The first book published on diseases of women after the organization of the American Medical Association was by Dr. C. D. Meigs, and although it ran through several editions, it would be considered a "back number" if compared with the present status of gynecology.

Obstetric societies were formed many years ago in some of the large cities, but the first gynecologic society organized was the Gynecological Society of Boston in 1869. Where obstetric societies existed gynecology shared with obstetrics in the attention which was devoted to it.

In 1870 the American Medical Association passed resolutions recommending that the establishment of chairs of gynecology, separate from obstetrics, be more generally adopted by medical colleges and schools throughout the country. To this great organization, therefore, credit must be given for this timely and important step along the line of greater attainments in this, the most important branch of medicine and surgery.

As early as 1871 there were thirteen medical colleges in the United States in which were full professorships of gynecology and obstetrics. Of this number there were seven schools with full professorships of diseases of women, incumbents teaching nothing else. At the present time every fully equipped medical school has a professor of gynecology whose lectures are devoted exclusively to diseases of women.[1]

A comprehensive review of the progress of obstetrics and gynecology in America during the past fifty years would require too much of the time of the Section. Perhaps sufficient reference has been made to meet the requirements of this occasion.

The last decade has been a period of advancement without parallel in the world's history. It is not within the power of tongue or pen to fittingly present the good accomplished in preventing suffering and saving life, the results of the progress along these branches of the healing art. Today health is restored and life saved where, in like conditions, a few years ago, patients were doomed to suffer on until death summoned them to eternal rest.

In making mention of the recent progress in obstetrics and gynecology, very little can be added to the recorded facts presented by my distinguished predecessors. During the past year operative procedures have in some quarters of the globe and by a few members of the profession, been severely criticised, and instead, palliative measures recommended. Conservatism has been and always should be the watchword of surgeons; just what conservatism stands for, is the all important question. Is it conservatism to permit our patients to suffer and eke out a miserable life, when it is within our skill to restore them to health and happiness? Our mission is most clearly defined by the motto: *Strive to prevent sickness, learn to restore*

---

[1] Compiled from the "American System of Gynecology."

health, and delight in prolonging human life by such methods as have been found the safest and surest, regardless of any dogma presented to us by the unfortunate or inexperienced members of the profession, who would have us follow their ipse dixit on the pretext that surgery was never intended to take the place of medicine. The writer is not to be understood as deprecating the teachings of any individual along any special line, neither that medicine has not a field of usefulness in the management of some of the conditions which we are constantly called upon to treat. But the important proposition for our consideration is: What can be accomplished by the conservative plans of our predecessors, which compare favorably with the modern methods of gynecologists? The answer is obvious. While it is true that much harm has been done in the past few years by ambitious and enterprising gynecologists, at the same time were we to compute the awful results of the other class of the profession who would recommend that operative measures should never be resorted to until the suffering patient is about to depart this earth to that country from whose bourne no patient ever returns, then the members of the profession would change their verdict. Is it not entirely pertinent to call a halt, and ask ourselves the question: What is the occasion for this constant play to the galleries, on the part of some of our professional brethren?

The use of vaginal antiseptic douches prior to parturition, which a few years ago were thought essential, are now discarded by many prominent obstetricians, unless it is apparent that there are present septic micro-organisms. All are agreed that surgical cleanliness should be rigidly observed in all other particulars. Too much stress can not be put on the importance of preparing the patient's body, bedding and room, with as much care as is observed in abdominal surgery. After parturition the genitals should be protected by antiseptic dressings.

Symphysiotomy, which has been so ably supported by Dr. Robert P. Harris of Philadelphia and others, has not, so far as the writer has observed, materially grown in favor during the past year. Porro's operation can be performed with quite as much safety to the life of the mother and at the same time gives more certain promise of complete restoration to health. The relative merits of these procedures must be left to individual obstetricians. The use of obstetric forceps to bring down the head to the soft parts, meets the approbation of many of our most experienced practitioners in cases where there is too much delay in labor, and the parturient is becoming exhausted.

Many recent reported cases of gestation complicated by ovarian tumors and other abdominal growths, which have culminated safely to mothers and children, go to teach that nature is equal to great things, and that for these conditions operative procedures may often be postponed till after parturition.

The use of the sharp curette in the treatment of endometritis, either acute or chronic, is now recognized as meeting the gravest conditions so common after abortions, and septic infection during labor.

The merits of electricity in the treatment of pelvic exudates and some forms of fibroid growths are still urged by numerous enthusiasts, and their opinion should receive the unprejudiced consideration of those whose experience has not afforded them the opportunities enjoyed by those whose work is along this line. It may truthfully be said that electricity has been discarded by many who formerly had much faith in its efficacy in the treatment of fibroids. At the same time it is not possible to write a final verdict relative to the future of this element in medicine. It has done incalculable harm in the hands of an army of followers and, unless it can be used by those whose experience has been such that the dangers are reduced to a minimum, it had better be discarded altogether. If it were possible for the profession to comprehend the awful condition resulting from tinkering with this most powerful and therefore dangerous element, its employment would be relegated to those only who have given sufficient time to investigate and master the intricacies of its action. To arrive at the comparative benefits of electricity in the treatment of conditions which are considered amenable to its influence, one must be thoroughly experienced in all that goes to make a careful and conservative specialist. The thought is, no one can be in a position to give an unbiased opinion regarding the merits or demerits of any plan of treatment until opportunity has been afforded to carefully investigate other methods for like conditions. The surgeon who never did anything but surgery for pelvic exudates and fibroids, would not be in a position to pronounce eternal damnation on electricity, even though he is quite familiar with some of the harm that has been done by this method, for he can not anticipate in every case what the condition was prior to its use or what it might have been without it. Neither can the electrician comprehend what may have been accomplished by methods entirely different. This important problem must, then, be relegated to a careful, conscientious and unbiased investigation, and the verdict will be recorded in the future.

It is quite apparent that much of the sentimentality connected with operations for diseased uterine adnexa has given place to more sober investigation relative to the results after these operations. It has become a universally recognized fact that patients whose lives have been spent in suffering, causing them to be burdens to themselves and anxious cares to their friends, are now with only an occasional exception restored to health and happiness by the skilled operator. This being a recognized fact, what is the cause of the hue and cry of those whose experience is too limited to comprehend the wonderful boon to suffering women afforded by the physicians who are giving their lives to this noble work. It is unnecessary to rehash the trite statement that "operators have manifested too much enthusiasm regarding the benefits to be expected from surgery." It is only injudicious surgery and surgical interference when other methods would promise more, that furnish topics for adverse criticism. To state it differently, we need a higher standard of excellence, a broader knowledge of etiology and pathology and a more conscientious, painstaking profession, whose whole aim in its work should be centered around the one all-important factor, namely, the best treatment for each individual patient regardless of financial and all other considerations. A few years ago it was thought wise to urge members of the profession residing in every town and at almost every cross-roads, to familiarize themselves with the operative procedures of pelvic surgery, but the more we become acquainted with the awful complications so very frequently met with, complications which baffle the most skilful operators, the more convincing it is that these obscure conditions should be referred to those whose large experience and careful training have fitted them for the great responsibility of thus dealing with precious human lives. It has now become a law of duty to refer our patients to those who have proved themselves competent to offer in their treatment the greatest assurance of success and the least risk to life. What conscientious physician would do otherwise? It always pays from every point of view, and, therefore, it has grown to be a custom which all recognize, to send patients to those who have shown by their attainments that they are especially fitted for the field they have chosen to follow. All that is needed, if the foregoing be true, is that greater excellence shall be attained, a broader knowledge of all that goes to make better diagnosticians, pathologists and therapeutists, electric, medical and surgical—elements to success that mean almost a lifetime in experience and a fortune in money to possess.

Considerable investigation is now being made by gynecologists with the view of testing the merits of leaving portions of the ovarian structure *in situ*, in order to prevent the establishment of the menopause, and in some instances with the hope of future pregnancy of the patient. Sufficient time has not been given this experimentation to afford us any definite conclusions. Doubtless some good may accrue from these methods in carefully selected cases. It should be the unvaried rule of all operators to preserve to the patient all her natural functions, unless perchance these functions are menacing to her health and endangering her life.

The advisability of removing the uterus, in every case of extensive suppurative disease of the adnexa, has grown in favor during the past year. The procedure has many earnest supporters and numerous opposers. In order to accomplish this end it is usually considered the safest to make the operation by the vaginal route. This question opens up an extensive field for discussion, and it has been found a most serious subject to dispose of satisfactorily.

The various methods for the removal of uteri for fibroids have had their share of attention by the profession, and no universally approved plan has been found. Each method has its merits in the hands of those who are attached to their special way, and all methods have their good points in properly selected cases. It would seem to be the ideal method where a hysterectomy is necessary and the patient has a fair amount of vitality, to remove the entire uterus. It has appeared to the writer that in a large per cent. of cases this operation may be done as safely as any other. That this method has not yet been perfected seems quite apparent, in view of the discussion relative to variations in the technique. Much adverse criticism has been indulged in on account of the fact that so much time is required in completing the toilet after the uterus is extirpated. This is perhaps an uncalled-for objection. My method is to grasp the anterior and posterior walls of the vagina as they are separated from the uterus with forceps, and as soon as the uterus is removed, pass with a curved needle a catgut suture through the lower portion of the stump of the right broad ligament and the anterior vaginal wall, the lower portion of left broad ligament and the posterior vaginal wall, then tie this puckering string as tightly or loosely as seems wise, keeping in view the propriety of passing a wick of gauze from above into the vagina for drainage. To execute this does not require more time than to write its description. Nothing more remains but to close the abdominal parietes and the operation is completed.

The use of pedicle clamps in vaginal hysterectomy has been the cause of much suffering and no little danger to life, and the aim should be to avoid their use if possible. It is more surgical and satisfactory to ligate with small strong silk the broad ligaments in sections and, after the uterus is extirpated, use slight traction on the attached ligatures, bring down below the peritoneum the stumps of the pedicle, and with a small curved needle carrying a catgut suture, the anterior and posterior walls of the upper portion of the vagina and the peritoneum are sutured in mass to the stump above the ligatures. Only one suture on each side is needed and they are introduced in the briefest time and your patient is ready for the introduction of a small wick of gauze drainage and tight or loose packing of the vagina with gauze. The ligatures, if properly used, will come away within twelve days and, in the meantime, they are out of the peritoneal cavity. No odor need be expected from the stump and the convalescence is established in twenty-four hours. This is my method and no case has been found where it could not satisfactorily be employed. It is always prudent to have the most approved clamps at hand, but not often necessary to use them.

Each year new evidence is added to justify the removal of the entire uterus for cancer of the cervical portion. All other methods of treatment have been found to be less promising and hysterectomy (thanks to the skill of modern gynecologists) is now one of the safest of major gynecologic operations. Amputation of the cervix by the galvano-cautery knife and the thorough use of a sharp curette is a method of dealing with cervical cancer which has some enthusiastic supporters and will doubtless prove of great value, especially in the management of conditions too grave for total extirpation.

The relative merits of Alexander's operation and hysteropexy for uterine displacements have been subjects for unusual discussion during the past year. Some of the histories of cases and arguments presented have been very instructive and if the individual operator can not decide upon the best method it will not be for want of an abundance of literature on this subject.

No absolute evidence has been furnished the profession relative to a permanent cure by ligating the uterine arteries for fibromata, further than the reports of a few cases, which have been temporarily relieved. It is possible that further time and experimentation will bring results commensurate with the enthusiasm of the originator of this procedure, a distinguished ex-chairman of this Section.

The administration of glandular extracts after the removal of uterine appendages and in conditions demanding nutritive tonics, is attracting much attention and are considered by many who have used them to possess much value.

Thorough ablution of the peritoneal cavity with normal salt solution for the treatment of tubercular peritonitis has been found so efficacious that this procedure should not be rejected in the gravest conditions.

Time will not permit of further reference to the many important gynecologic and obstetric questions, which will continue for years to furnish matter for scientific discussion.

Before concluding, it gives me great pleasure to make honorable mention of this wonderful city, the home of many great and good men, who have done, and are continuing to do, so much for the advancement of the science of obstetrics and gynecology. Without deprecating other cities, and other honorable, earnest and conscientious men, Philadelphia may be given the palm for being the home and field of research, of as great and honorable men as have ever wielded a pen, handled a scalpel, or disseminated from the rostrum the sterling truths and doctrines of our science. The names of some of those who have made medical and surgical records were mentioned in connection with the brief review of some of the work which was done earlier in the history of our ASSOCIATION. Nothing could afford me more pleasure than to record at length the work and special merits of all of Philadelphia's obstetricians and gynecologists. My personal acquaintance with some of them makes it nearly impossible to refrain from mentioning those who were my teachers and friends, when only a few years ago I was seeking knowledge in this special field, and received from them such earnest and thorough instructions that, whatever of success may have come to me from that time till the present hour, to the kindness of these great masters is due the entire credit.

Finally, I desire to attempt feebly to express my endless gratitude for the great honor of having been elected Chairman of this Section on this occasion. My sensibilities would, indeed, be obtuse, if I was not inexpressibly thankful for the honor. All that I can say will be merely words. My appreciation is heartfelt and genuine. No greater honor can be conferred on a member of the profession than to be chosen to preside over a body of men so cultured and distinguished in the profession as are you who compose the members of this Section of the AMERICAN MEDICAL ASSOCIATION.

ORIGINAL ARTICLES.

THE DIFFERENTIAL DIAGNOSIS OF SURGICAL LESIONS IN THE RIGHT HALF OF THE ABDOMEN AND PELVIS, WITH ESPECIAL REFERENCE TO THE DIAGNOSIS OF APPENDICITIS.

Presented to the Section on Surgery and Anatomy, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1–4, 1897.

BY GEORGE RYERSON FOWLER, M.D.
PROFESSOR OF SURGERY IN THE NEW YORK POLYCLINIC; SURGEON TO THE METHODIST EPISCOPAL; SURGEON-IN-CHIEF TO THE BROOKLYN HOSPITAL.
BROOKLYN, N. Y.

Inflammatory and other lesions in the right half of the abdominal and pelvic cavities have of late years assumed an increased importance. This is owing to the prominence given to the disease appendicitis, as well as to those inflammatory conditions of the adnexa in women to which the broad term pelvic inflammation is applied.

There can be no question in the minds of those who have given the subject much attention that the inflammatory conditions of the vermiform appendix constitute the most important surgical lesions of the abdominal cavity. This is true both for the male and female sex. While it is true that in the female it is less frequent in its occurrence than in the male, and in addition, the female is subject to inflammatory suppurative conditions peculiar to the sex, yet in estimating the importance of an affection we must take into account its life-destroying characteristics, the difficulties encountered in its diagnosis, the necessity for prompt action in its early treatment and for highly skilled surgical help in its later stages in addition to the frequency of its occurrence. So far as the danger to life in an unrecognized case is concerned, this is as great in the female as in the male. In the matter of difficulties of diagnosis, these are greatly increased in the female, owing to the possibility of errors arising from the presence of organs in the neighborhood that take on suppurative inflammation, which, in not a few instances, closely simulate that of the appendix; or possibly the occurrence of diseased conditions of these as a complication. The necessity for careful watching and prompt action in appendical lesions, as compared with those of the adnexa, is another feature which emphasizes the importance of the affection in the female. The mistake of postponing interference is more remote in the male than the female, owing to the absence of that element of doubt which must frequently exist in the latter. Upon the basis of these considerations it may be claimed with reason that inflammatory conditions of the appendix in the female lose none of their importance because of the lesser frequency with which women are attacked with the disease as compared to men, since it is in these very cases that errors in diagnosis with resulting failure to operate are most likely to occur. On the other hand, the preponderance of males loses its relative importance when the comparative ease of diagnosing the affection in this as compared with the female sex is taken into account.

All conditions which may be mistaken for appendicitis in the male, with the sole and rare exception of an inflamed right undescended testicle, occur likewise in the female. Some of these occur with even greater frequency in women, these constituting additional sources of error in the case of the latter sex. Of these latter may be particularly mentioned cholelithiasis and gall bladder affections, such as impaction of gallstones and resulting dropsy and empyema of the gall bladder, hyperacute inflammation and occasionally gangrene of that viscus, and angulation or torsion of the ureter occurring in connection with a movable right kidney. Gallstones occur nearly five, and floating kidney six or seven, times more frequently in women than in men. With special reference to the diagnosis of right-sided lesions it should be borne in mind that the right kidney is affected four times as frequently as the left.

When all these circumstances are taken into consideration it will be found that appendical lesions rank first in importance among the surgical affections of the abdominal and pelvic cavities.

With these facts before us the logical course to pursue in the present presentation of the subject will be the consideration of the diagnosis of appendicitis, and the differentiation of this disease from other inflammatory conditions, as well as such neoplasms as may simulate it.

Appendicitis, although in the great majority of cases pursuing an acute course from the commencement to the end of the attack, may be subacute or chronic in the beginning, afterward developing an acute condition; rarely it may remain subacute or chronic throughout its entire course; occasionally a chronic condition may follow an acute attack with the supervention of subacute, acute or even hyperacute exacerbations. Clinically, therefore, the cases may be divided into the acute, the subacute, and the chronic. It is true that the acute cases may be still further subdivided into the hyperacute and the subacute, and the chronic division into cases which are chronic from the commencement (and remain without acute or subacute exacerbations, a rare occurrence in my experience), and those which follow an acute attack and are subject to more or less frequent relapses of the original acute condition. But for the practical purposes of the surgical diagnostician these subdivisions may be disregarded.

For the sake of laying a proper foundation for our study of the subject I will briefly call attention to the principal points to be borne in mind in the objective and subjective symptoms of these clinical forms of the disease.

Acute appendicitis.—The acute form of appendical inflammation is characterized by: *a*, sudden onset; *b*, colicky or cramping abdominal pains; *c*, vomiting; *d*, localized pain and tenderness; *e*, rigidity of the right rectus muscle; *f*, the presence of a tumor; *g*, fever. The pain is referred at the commencement, in the vast majority of cases, to the region immediately above the umbilicus, but finally becoming diffused in the entire abdominal region. If the patients are asked to point out the place where the pain was first felt they will most frequently indicate the center of the epigastrium. This fact has been a very frequent source of error, particularly when considered in conjunction with the symptom next to be considered. The occurrence of nausea and vomiting is of such frequency as to lead me to pursue the inquiry as to this symptom if it is not mentioned by the patient, and to look upon a case in which it is absent as being irregular or atypical in its development. The pain may be finally localized in the right iliac region, but the usual hypodermic injection which the patient receives at the hands of the attending physician is sufficient to allay all pain at first, both epigastric and iliac, and therefore this symptom does not count for much by the time the surgeon sees the case. Localized tenderness in the right iliac region however, is not so easily abolished although markedly diminished and perhaps more difficult of differentiation from the existence of a certain amount of sensitiveness which many observers have noted as being present in this region in conditions of health, or in connection with abdominal or pelvic lesions other than those of appendical origin. and in hysteric women. Rigidity of the right rectus muscle at its lower part is the result of an instinctive effort to prevent this portion of the muscular abdominal wall from taking part in the respiratory movements. It may likewise be prevented from manifesting its full significance by the attempts made to allay the pain by the administration of opium. The rigidity of neurotic subjects with hypersensitive abdominal surfaces should not be confounded with that arising from underlying inflammation. A tumor in the ileocecal region makes its appearance after the first or second day, and is situated directly opposite to and close upon the anterior superior spinous process of the ilium, or below this point opposite the upper concave portion of Poupart's ligament. When fully formed its presenting area corresponds to that of the superficial tenderness present. Fever is not marked in the commencement; some acceleration of pulse and elevation of temperature however is generally observed.

The variations from the usual and typical characteristics of the acute attack consist of: 1. The occurrence of primary, general abdominal pain rather than localized pain in the epigastrium, or a localization of the pain in the right iliac region in the beginning of attack. 2. Absence of vomiting due to the fact that the stomach is quite free from ingesta, although even under these circumstances nausea will be complained of, and the administration of some domestic cathartic, usually a dose of caster oil, will be almost certain to bring on vomiting. 3. Localized pain will usually be abated, and right iliac tenderness diminished by the administration of opiates. Cases of rapid gangrene of the organ may be unattended by pain in the region of the appendix in the beginning. 4. Opiates may so modify the respiratory movements as to render unavailable for purposes of diagnosis rigidity of the right rectus muscle, as well as to destroy that reflex tension of this muscle so frequently observed when pressure is made upon the wall of the abdomen in the ileocecal region. 5. The presence of a tumor is not usually available for diagnostic purposes until after twenty-four hours at the earliest; it is usually delayed until after forty-eight hours. In an exceptionally long appendix inflamed at its digital extremity, the tumor may be located elsewhere than in the ileocecal region. If the organ points downward and inward the tumor may be in the pelvis; if directly inward, behind the linea alba or beneath the left rectus muscle below the umbilicus; if upward and inward, behind the right rectus muscle and on a level with or even above the umbilicus; if directly upward and under the colon it may be found just beneath or at the usual site of the gall bladder; if upward and outside of the colon it may be found at varying points from the level at the crest of the ilium to the last rib. In deviations from the normal anatomic disposition of the ileocecal junction still further variations of position of the tumor may occur. In this manner cases of left-sided appendicitis, deep pelvic abscesses of appendical origin, and appendical abscesses in the right hypochondrium are to be accounted for. In the same manner and for the same reasons varying points of maximum tenderness occur. 6. *The pulse rate may be but slightly affected in the commencement, and ulceration and perforation of the organ may occur at any time during an exceptionally mild attack, with practically no rise of temperature.*

2. *Subacute appendicitis*.—In this form, as the term implies, the onset is less acute. The attacks may be so mild as to pass for a simple indigestion, or intestinal colic. A number of cases of indubitable appendicitis with hyperacute attacks have come under my observation, in which a history of preceding attacks that had been treated for "colic" or "indigestion" was obtained. Indeed, I have never known subacute appendicitis to be mistaken for anything else. The error is not a grave one, provided opium be not given and the possible onward course to the development of an acute or a hyperacute attack masked. The inflammatory action may now and then reach a sufficiently high grade to call attention to the ileocecal region. Tenderness at the site of the appendix may usually be elicited. There is usually no tumor to be found. In the cases of appendicitis that have come under my care, in which a history of preceding subacute attacks has been obtained, there has usually been found at the operation either one or more hardened fecal masses in the appendix, or an accumulation of secretion; the latter sometimes to the extent of an empyema, the secretion having undergone suppurative changes. In the

latter instances there have been found either partial or complete obliteration of the appendiculo-cecal orifice. This condition may be acquired as the result of previous disturbances, or be congenital in its origin. In any event, if permitted to continue, these cases of subacute appendicitis will almost of a certainty eventuate in an acute attack.

3. *Chronic appendicitis.*—Cases coming under this head may, as a rare circumstance, be chronic from the beginning. In the vast majority of cases they either eventuate from repeated subacute attacks, or follow a well defined acute attack. The characteristic clinical picture is marked by tenderness in the ileocecal region, with or without the presence of a tumor. The latter is usually the case if an acute attack has preceded the symptoms, particularly if this has been recent. The tumor is the result of an inflammatory environment of the organ; exceptionally an empyema of the organ may be sufficiently pronounced to constitute a tumor.

Practically, the differential diagnosis will lie between lesions of gall bladder origin; those originating in the intestine and not of necessity involving the appendix; and tubo-ovarian disease.

Of the gall bladder lesions, those involving the simple passage of a gallstone along the ductus communis choledochus may simulate the occurrence of acute appendicitis. Here the pain may be referred to the epigastrium, as in appendicitis; it radiates, however, toward the shoulder and the angle of the scapula. In the vast majority of cases it starts from the gall bladder as a fixed point. Whatever tenderness exists is referred to the lower border of the ribs and the region of the gall bladder. A gallstone impacted in the cystic duct and followed by dropsy of the gall bladder may give rise to some of the symptoms of chronic appendicitis; the downward projection of the gradually distended gall bladder may give rise to a tender tumor below the level of the umbilicus and beneath the right rectus muscle; infection of the gall bladder contents by bacterial migration through its walls, enervated by extreme pressure from within, may give rise to empyema of the gall bladder and cholecystitis, which in its turn is followed by febrile movement, abdominal pains and increased sensitiveness, all of which in their subjective symptomatology, may simulate appendicitis. On the other hand, even without the downward displacement of the gall bladder, the presence of an unusually long and vertically placed appendix, when inflamed, may complicate the differentiation between this and a gall bladder lesion.

Of the intestinal lesions in the ileocecal region, those involving an acute obstruction or a perforation of the bowel are the most important, as well as, in some instances, difficult of diagnosis, and these require a sharp differentiation and prompt operative treatment. Here the absence of a tumor can not be of practical utility in the diagnosis, since its appearance may be postponed for two or three days, and in the meanwhile the patient will certainly lose the chance of recovery offered by operation. Of less importance are the chronic obstructive conditions and neoplasms, for the reason that these of themselves do not, as a rule, urgently demand operative treatment when first discovered, nor do the appendical conditions for which they may be mistaken require that promptness in diagnosis and celerity of action necessary for the proper care of cases of acute appendicitis. The presence of a comparatively insensitive movable tumor characteristic of a neoplasm of the bowel, or of a doughy mass suggestive of impacted fecal matter, on the one hand, and an immovable and tender tumor on the other, to say nothing of the information to be gained by a close scrutiny of the history, offer a sound working basis for reasoning out the true condition present.

A close study of the question impels me to the belief that the surgical clinician will probably be called upon oftener to differentiate between appendicitis and tubo-ovarian lesions, than between the former disease and all others for which it is likely to be mistaken, combined. As a result of a somewhat extensive experience in appendical lesions, as well as in those conditions of the uterine adnexa that have been most frequently mistaken for the former, I would emphasize the following as the most important points to be borne in mind in the differential diagnosis:

Frequency.—Based upon the study of a large number of cases, the proportion is as 1 to 4 (males 80 per cent., females 20 per cent.).

History of the attack.—In a large proportion of cases the history in appendicitis is that of an acute onset. In tubo-ovarian disease a previous history of infection, with endometritis, salpingitis, ovaritis and pelvic peritonitis, and coincident progressive menstrual disturbances, may generally be obtained. Further, in considering the possibility of ectopic gestation in a given case, the fact that the diagnosis may be obscured, in an unmarried woman, by false statements made by the patient regarding the menstrual history, should not be lost sight of.

Pain.—In appendicitis the pain is usually acute and radiating, while in adnexal disease it is more apt to be dull and localized. Three considerations having a bearing in this connection should be borne in mind, however. The first relates to the fact that in subacute and chronic appendicitis the pain may be dull and localized; the second, that in acute appendicitis the pain may have been masked by the injudicious administration of opium; and the third, that the supervention of an acute exacerbation of a chronic pelvic inflammation may give rise to pain sufficiently acute and severe to simulate appendicitis.

Vomiting.—This is exceedingly common in appendicitis, and of much less frequency, relatively, in adnexal disease.

Tenderness.—In the great majority of cases the tenderness, in appendicitis, is located at the site of the appendix, and in tubo-ovarian disease it may be traced to the adnexa. The maximum point of tenderness in appendicitis corresponds to or above the level of the anterior superior spinous process of the ilium, while in adnexal disease it is located well below this level. Considerable force is required to elicit the point of tenderness by the vaginal touch in appendicitis; this is easily accomplished by this route in adnexal disease. *Per contra*, the tenderness brought out by external pressure in the last named, is nothing like as great as that by the vaginal touch, while considerably less pressure in the appendical region will show the latter to be extremely sensitive in appendicitis. Movements of the uterus by the examining finger do not, as a rule, give rise to complaints of pain from the patient, in appendicitis, while they are almost certain to do so in adnexal disease. The nearer proximity of the tenderness to the median line and bony anterior pelvic wall, examined either externally or by the vagina, the greater the chance of pelvic inflammation being present, and *vice versa.* The remarks concerning the possibility of masking pain by opium apply with equal force to the symptom of tenderness.

Chill or rigors.—A chill is of infrequent occurrence in appendicitis, and is a not uncommon symptom in acute exacerbations of adnexal disease.

Fever.—Fever is present in appendicitis, although its grade is of no service in estimating the severity of the attack, particularly in cases in which the temperature is but slightly elevated, and the pulse not markedly accelerated. It may be absent, or nearly so, in chronic adnexal lesions, until a spread of previously existing infection, or the introduction of fresh infectious agents is announced by its presence.

Muscular tension.—While rigidity of the right rectus muscle is occasionally absent in appendicitis, it is almost invariably so in adnexal lesions, unless the latter is complicated with considerable peritonitis. So marked is this difference, as between the two conditions, that this sign is almost pathognomonic in the differential diagnosis. It is rarely marked in tubo-ovarian disease, although like the symptoms of pain and tenderness, it may be masked by opium in appendicitis.

Tumor.—Tumor may be present after the second or third day in appendicitis; rarely before the latter. In tubo-ovarian disease it is usually present when the surgeon is called in. In appendicitis its usual location is beneath the right rectus muscle and opposite the anterior superior spinous process of the ilium, or to the outer side of this area, where it is easily made out by abdominal palpation. In tubo-ovarian disease it is more easily found by vaginal touch, while abdominal palpation may fail to reach it altogether because of its low position behind the pubic arch. It is rare that a tumor of appendical origin can even be felt by the vaginal touch, much less satisfactorily palpated by conjoined manipulation.

Course.—Appendicitis usually follows an acute course, while in adnexal lesions a subacute or chronic course is the rule. In chronic appendicitis there is almost always a history of at least one acute attack and relapses are common as long as there is any impairment of the nutrition of the organ, even with but slight infection present. In adnexal disease, while the chronicity of the course may be disturbed by the supervention of acute exacerbations, it is rare to obtain in the history a statement of a well defined and sudden onset. The practitioner should be well on his guard to distinguish between the last named and chronic relapsing appendicitis. The subjective symptoms alone will not suffice for this, and physical examination only can reveal the true condition of affairs. Rupture of a pyosalpinx offers a grave condition and presents great difficulties in differentiation between this and perforative peritonitis of appendical origin. Fortunate it is that to open the abdomen promptly in either case offers the patient the best chance for recovery.

Of the rarer conditions known to simulate appendicitis may be mentioned a case in which a lithopedion escaped from a right Fallopian tube (Martin of Berlin), a fibromyoma of the ileocecal region (Sonnenburg), a small suppurating dermoid (Bergmann), a ruptured right rectus muscle occurring while the patient was under the influence of liquor, and a ruptured gall bladder under the same circumstances (my own cases). I have been compelled to reopen the abdomen a second time in two cases in which adhesions formed between the stump of a removed right ovary and tube and the appendix gave rise to symptoms of appendical origin. Since these experiences I have made it a rule to remove the appendix when intraperitoneally located, in all cases of abdominal section. Further, one should not fail to take into account the possibility of the coexistence of chronic and acute lesions of the adnexa and appendix, or the simultaneous presence of an acute lesion of the one and a chronic lesion of the other. The presence of the appendiculo-ovarian ligament of Clado furnishes a route of bacterial migration from the intestine to the right ovary. The presence of the bacterium commune coli has been demonstrated by Kiefer in an ovarian abscess, and Dr. Robert L. Dickenson, one of my colleagues at the Brooklyn Hospital, recently operated on a case in which the appendix was directly attached to the right ovary, inflammatory conditions of both coëxisting. The focal lesion in this case probably existed in the appendix.

Finally, one should not fail to take into account the difficulties which may present themselves in establishing the diagnosis of appendicitis in the male sex under circumstances of an exceptionally long appendix passing deeply into the lesser pelvis. Sonnenburg reports two such cases where the primary abscess was situated in the Douglas *cul de sac*, in which access was gained to the suppurating mass through an opening made between the rectum and bladder. The following list embraces some of the most important of the conditions which have been mistaken for appendicitis within my own knowledge or have been reported upon good authority:

Acute conditions.—Subphrenic peritonitis, gall bladder lesions, acute intestinal obstructions, paratyphlitis, rupture of right rectus muscle, ruptured pyosalpinx, ruptured ectopic gestation, acute torsion of right ovarian cystoma, acute torsion of right hydrosalpinx, right-sided hemato-salpinx, acute peritonitis, paroxysms of pain due to right movable kidney.

Chronic conditions.—Abscess in the abdominal wall, impacted ureteral calculus, fecal impaction, tubo-ovarian inflammation, carcinoma in the ileocecal region, retroperitoneal sarcoma presenting in the right iliac fossa, neoplasms of the right ovary, right-sided chronic salpingitis with recurring acute exacerbations, fibromyoma in the cecal region, adhesions following operations on right adnexa.

In order to facilitate the study of the differential diagnosis of the surgical lesions of the right half of the abdomen and pelvis, I have prepared the following:

ACUTE APPENDICITIS.

Anamnesis, etc.—Most frequent in males (80 per cent.) Rare at the two extremes of life. Previous good health immediately preceding present attack as a rule. History of previous attacks in a certain proportion of cases. Sudden onset.

Pain.—Cramping or colicky and rather constant. Most acute in epigastrium and region about the umbilicus; more or less diffused later on, and may finally center in right iliac region.

Nausea and vomiting.—Present in great majority of cases. Usually ceases when contents of stomach are vomited, unless extensive peritoneal inflammation occurs early. Rarely persistent and intractable.

Tenderness.—Markedly localized in the center of the right iliac region at the commencement, but becoming more diffused with the extension of the peritoneal inflammation. Is frequently marked along the middle of Poupart's ligament. In the rare cases of non-descent of the cecum the tenderness may extend to the parts immediately below the umbilicus or be located to the left of the median line. Present, although in lesser degree in the direction of the ascending colon particularly when the appendix lies to the outer side of the colon and points directly upward. When the appendix is extraperitoneally situated the tenderness may be pronounced in the lumbar region.

Muscular tension.—Right rectus muscle tense at its lower part. Rigidity pronounced in proportion to peritoneal involvement.

Tumor.—Rarely present before the lapse of forty-eight hours following the attack and may be delayed until the third or fourth day. Its location is quite constant in the right iliac region but may vary with abnormalities in the location of the cecum. Is immovable and usually rounded and smooth.

Impairment of function of intestinal canal.—Distension of coils of intestine in the neighborhood. Bowels may be moved by enemata and cathartics before diffuse septic peritonitis sets in.

Fever.—Slight elevation of temperature and acceleration of pulse in the commencement but not a trustworthy guide in their relation to the threatened severity of the attack, particularly when these symptoms are not marked.

SUBPHRENIC PERITONITIS.

Anamnesis, etc.—History and mode of onset will vary with source of peritonitis. Arises most frequently from perforating ulcer of stomach or duodenum; next in frequency from the appendix. Abscess of the kidney, cholecystitis, lesions of the pancreas, and perforation of intestine elsewhere, furnish examples.

Pain.—Pain severe and more constant and less colicky and lancinating in character than in appendicitis. Located in upper part of abdomen.

Nausea and vomiting.—Not marked unless peritonitis becomes general. When due to ulcer of the stomach the vomiting precedes the attack.

Tenderness.—Localized in epigastrium or hypochondrium.

Muscular tension.—Limited to region above umbilicus.

Tumor.—Not discernible until abscess forms. Then demonstrated by percussion. Littre's diaphragmatic sign (drawing in of the intercostal spaces one after another, as contraction of the diaphragm takes place) is of importance.

Impairment of function of intestinal canal.—Not marked.

Fever.—Fever varies with infection. With formation of abscess becomes more marked.

GALL BLADDER LESIONS.

Anamnesis, etc.—Cholelithiasis, the most common underlying cause, occurs five times as frequently in females as in males and in women over thirty as a rule. Dropsy and empyema usually preceded by indefinite feelings of distress referred to region of gall bladder; less frequently by recurrent attacks of hepatic colic, not necessarily accompanied by jaundice. Perforation by gallstone, supervention of suppuration in dropsy, and the occurrence of acute inflammation of gall bladder marked by sudden onset.

Pain.—Less acute and colicky in dropsy and resulting empyema than in acute inflammation of gall bladder and perforation from gallstones. In the latter equally so with appendicitis. More distinctly localized in the commencement in all these than in appendicitis. Generally referred to right hypochondrium.

Nausea and vomiting.—Absent as a rule.

Tenderness.—Present. Marked in acute inflammation and perforation. Less in empyema. Occupies a somewhat larger area in the right hypochondrium than that which is characteristic of appendicitis in the right iliac region, but may extend below the line of the umbilicus when the gall bladder is greatly distended.

Muscular tension.—Upper portion of right rectus, and sometimes both recti, more or less rigid.

Tumor.—Generally present when patient comes under surgeon's care. Is rounded, smooth, immovable, and usually found at normal site of gall bladder. Exceptionally and under circumstances of considerable distension, may reach below umbilicus.

Impairment of function of intestinal canal.—None as a rule. There may be some distended coils in the neighborhood.

Fever.—Fever present and pulse correspondingly accelerated.

ACUTE INTESTINAL OBSTRUCTION.

Anamnesis, etc.—*Invagination:* Two-thirds of the cases occur in males, one-third in females. Three-fourths of all cases of invagination are in the neighborhood of the cecum. It is especially an accident of the young (34 per cent. under 1 year and 56 per cent. under 10.) *Volvulus:* Eighty-seven per cent. occur in large intestine; of these one-half occur in the neighborhood of the sigmoid flexure, and less than one-third in the ileocecal region. Occurs in males in the proportion of two to one. Most frequently absent between the ages of 30 and 40. *Obstruction of abnormal contents or foreign bodies:* Almost 50 per cent. due to gallstones; 43.5 per cent. due to fecal impaction; remainder due to enteroliths and substances swallowed. Obstruction by gallstones three times as common in females as in males and usually in patients past 50. The ileocecal region the most frequent seat. Usually preceded by hepatic colic, jaundice or symptoms pointing to the entrance of the gallstone into the intestine by ulceration through the gall bladder and bowel wall. *Internal strangulation:* The most frequent cause of intestinal obstruction (35 per cent. of all cases); 90 per cent. in the small intestine; 83 per cent. in lower abdomen; 67 per cent. occur in the right iliac fossa; 70 per cent. occur in males; 40 per cent. occur between the ages of 15 and 20; of these, inflammatory adhesions cause the strangulation twice as often as vitelline remains (Meckel's diverticulum and persistent remains of vitelline blood vessels). Relatively uncommon in childhood, when it does occur is usually caused by vitelline remains. *Strangulated diaphragmatic hernia* occurred in 10 per cent. of 1,134 cases of internal strangulation (Lichtenstein). Usually regarded as a very rare condition. Internal strangulation when due to *adhesions* may be preceded by history of some inflammatory abdominal or pelvic lesion, recent or remote. *Invagination* and *volvulus* give us preceding history. *Obstruction by gallstone* is usually preceded by jaundice, hepatic colic or symptoms pointing to entrance of the gallstone into the bowel by ulceration through the gall bladder and bowel wall. In strangulated diaphragmatic hernia there is almost always a history of severe injury, although the original condition may be congenital.

Pain.—Severe and intermittent at first; finally rather constant, with acute exacerbations. Location has no diagnostic value in differentiating between the different forms; most frequent in the neighborhood of the umbilicus. Does not become localized.

Nausea and vomiting.—Frequent and persistent. When contents of stomach are vomited the vomitus is first bilious, then yellow and finally fecal.

Tenderness.—Limited tenderness less easily differentiated.

Muscular tension.—General rather than limited to lower portion of the right rectus.

Tumor.—Rarely present except in invagination, when it may be fixed after inflammatory action occurs. Occasionally found in obstruction by foreign bodies, when it is mobile.

Impairment of function of intestinal canal.—Constipation complete; passage of flatus absent. Tenesmus in 15 per cent. of cases of volvulus and in 55 per cent. of invagination. Bloody discharges. Tympany present, increasing with the duration of the obstruction.

Fever.—Pulse more or less accelerated, increasing in frequency with duration of obstruction. Absence of fever in the beginning rather characteristic.

PARATYPHLITIS.

Anamnesis, etc.—Exceptional and of rare occurrence, as compared with appendicitis. Follows inflammatory condition of cecal wall (typhlitis) and of its serous covering (perityphlitis), having its origin in fecal accumulations. History of loss of appetite, disturbance of digestion and constipation. More or less sudden in its occurrence, but less abrupt than in appendicitis. The first acute symptoms may be due to ulcerative perforation of the bowel wall.

Pain.—Dull and constant, and less diffused as compared with that of appendicitis, usually limited to right iliac region from commencement.

Tenderness.—Present and limited to area involved. Less acute than in appendicitis.

Muscular tension.—Marked in proportion to acuteness of the symptoms.

Tumor.—Present early in cases of stercoral origin, in which case the tumor will present as a sausage-shaped mass in the cecal region, which may be indented with the finger. When suppuration has taken place tumor will present same characteristics as in suppurative appendicitis.

Impairment of function of intestinal canal.—Constipation, overcome by cathartics, which in the early stages of the affection sometimes relieve all the symptoms.

Fever.—Slight fever in commencement. With advancing suppuration, becomes more pronounced.

RUPTURED PYOSALPINX.

Anamnesis, etc.—Comparatively infrequent. Pelvic inflammation. Gonorrheal or other infection, pelvic distress and pain varying in intensity, and menstrual disturbances. Onset sudden.

Pain.—Severe, diffused, constant and of long dur

Nausea and vomiting.—Rarely present or marked until diffuse septic peritonitis sets in.

Tenderness.—Extreme and general below umbilicus. Location of tenderness made most easily manifest by vaginal touch.

Muscular tension.—Absent until diffuse septic peritonitis occurs, which supervenes rapidly in case of rapid emptying of abscess cavity.

Tumor.—Sensitiveness usually so great that induration can only be felt by vagina, and then not always satisfactorily as a distinctly defined tumor.

Impairment of function of intestinal canal.—Not present until intestinal paresis and finally complete paralysis of peristalsis from diffuse septic peritonitis occurs.

Fever.—Steady and marked increase in pulse rate and rise of temperature.

RUPTURED ECTOPIC GESTATION—PELVIC HEMATOMA.

Anamnesis, etc.—More frequent in its occurrence than formerly supposed (35 times out of 3500 autopsies; Formad). Less frequent in young primiparas than in older multiparas. Symptoms referable to normal pregnancy (absence of menses, nausea, swelling of breasts, softening of cervix, etc). A bloody vaginal discharge may take place subsequently to last menstruation. Labor-like pains, bloody vaginal discharge and if the pregnancy is advanced the casting off of a decidua may precede the rupture of the fetal sac. Onset sudden with symptoms of collapse and internal hemorrhage.

Pain.—Acute and diffuse over lower portion of the abdomen. Is of short duration.

Nausea and vomiting.—Absent.

Tenderness.—Not localized, if present.

Muscular tension.—Absent until peritonitis sets in, then general.

Tumor.—If patient survives primary rupture sufficiently long, the physical signs of pelvic hematocele or pelvic hematoma may be found. These distinguishable by conjoined manipulation and are more easily determined from the vagina than from the abdominal surface. In many cases identification of tumor not at once possible even under an anesthetic.

Impairment of function of intestinal canal.—None.

Fever.—With profuse hemorrhage, pulse rapid and feeble, temperature subnormal, later rising slightly. General symptoms of acute anemia present, such as pallor, thirst, air-hunger, etc.

ACUTE TORSION OF RIGHT OVARIAN CYSTOMA.

Anamnesis, etc.—Occurs in about 10 per cent. of cases of ovarian cystoma. Occurs most frequently in small tumors. If tumor is large a history of such may be obtained. In two out of four cases observed by the writer the symptoms came on while the patients were leaning over a wash tub engaged in rubbing clothes upon a washboard. Sudden onset.

Pain.—Violent pain in the right side of abdomen.

Nausea and vomiting.—Generally present.

Tenderness.—Considerable area of tenderness below and to the right of the umbilicus.

Muscular tension.—Present and somewhat general. Localized rigidity not marked.

Tumor.—Present. Increases rapidly in size.

Impairment of function of intestinal canal.—Absent.

Fever.—Fever absent in the commencement.

TORSION OF RIGHT-SIDED HYDROSALPINX.

Anamnesis, etc.—Rare. The writer has seen but one case and finds no other in the literature. Disturbances of menstruation (frequent, painful, and prolonged flow). Pelvic distress incident to pelvic inflammation in general. Sudden onset.

Pain.—Acute pain referred to entire right side of pelvic region.

Nausea and vomiting.—Absent.

Tenderness.—Localized and marked just above bony brim of pelvis.

Muscular tension.—Absent.

Tumor.—Located just behind insertion of right rectus muscle and extending to the right about half way to Poupart's ligament.

Imparment of function of intestinal canal.—None.

Fever.—Pulse accelerated. No fever.

RIGHT-SIDED HEMATOSALPINX.

Anamnesis, etc.—Infrequent in occurrence. Previous history of menstrual disturbance, the flow usually appearing too frequently and lasting beyond the usual time. Dysmenorrhea. Onset of symptoms rather sudden and usually due to escape of blood from distal end of tube and resulting localized peritonitis.

Pain.—Not marked save when peritonitis occurs. May be at first localized, afterward referred to the pelvic region generally.

Nausea and vomiting.—Absent.

Tenderness.—Not well marked by palpation from the abdominal surface. If present is below the level of the middle of Poupart's ligament. Usually easily elicited by the finger in the vagina.

Muscular tension.—Absent as a rule.

Tumor.—If felt from without is well below the level of the middle of Poupart's ligament. Is much more readily distinguished from the vaginal than from the abdominal surface.

Impairment of function of intestinal canal.—None.

Fever.—Varies with the acuteness of the inflammatory conditions. Fever *not* a marked feature.

ACUTE PERITONITIS.

Anamnesis, etc.—Frequency depends upon affections underlying the attack. Idiopathic or primary peritonitis probably never occurs. *Perforative peritonitis* usually results from acute appendicitis, typhoid ulceration, foreign bodies, penetrating wounds, intestinal obstruction, strangulated hernia, blows upon the abdominal surface, and excessive handling of the intestines in the course of operations involving opening of the abdominal cavity. *Infective peritonitis* is caused by extension of infection from inflammatory lesions of the uterus and Fallopian tubes in the female, suppurative hepatitis, gall bladder affections, suppurative kidney lesions, and operative infection. *Symptomatic peritonitis* occurs in the course of an acute or chronic disease such as pleurisy or pneumonia. *Tubercular peritonitis* usually pursues a chronic course. *Syphilitic*, *rheumatic* and *gonorrheal* peritoneal infection very rare.

Pain.—Varies with the virulence of the infection and the rapidity of the extravasation. At first localized, afterward becoming general; may not be sufficiently prominent to occasion complaint.

Nausea and vomiting.—Early, persistent and intractable nausea and vomiting almost invariably present. Contents of stomach first vomited, then bile, and finally in fatal cases, material from small intestine. Hemorrhage from mucous membrane causes a dark brown vomitus.

Tenderness.—At first localized at point of original infection, then becoming generalized.

Muscular tension.—Progressively increases from original focus of peritoneal infection until in diffuse septic peritonitis the entire muscular abdominal wall becomes excessively rigid.

Tumor.—None present in diffused peritonitis. When more or less circumscribed a sero-purulent collection may occur in the course of time and give rise to a tumor.

Impairment of function of intestinal canal.—Early occurrence of paralysis of peristalsis, and resulting intractable constipation. Distension due to the forcing of gas from the still functionally unimpaired portion of intestinal canal into the paralyzed coils. In some instances the entire tract is almost simultaneously paralyzed, in which case distension may be less marked or absent.

Fever.—The pulse is rapid, out of all proportion to the rise of temperature. Fever is present as a rule.

PAROXYSMS OF PAIN DUE TO RIGHT SIDED MOVABLE KIDNEY.

Anamnesis, etc.—Proportion of women affected greatly in excess of males. Most frequent between the thirtieth and fortieth years. Right kidney twelve to thirteen times more often affected than left. Child-bearing appears to have a decided influence in its production. Previous history of symptoms of movable kidney, viz., dragging, weight and dull pain in loin and side of abdomen, aggravated by exercise and relieved by rest. In women, suffering is increased by menstruation and pregnancy. Occasional sense of something moving. History of previous attacks of paroxysmal pain resembling renal colic. Sudden onset if torsion is present, accompanied by suppression or marked diminution of the quantity of urine.

Pain.—Paroxysmal. Referred to the renal region and extending in the course of crural or sciatic nerves.

Nausea and vomiting.—Frequently present during paroxysm.

Tenderness.—Not a marked symptom. Palpation gives rise to a peculiar sickening sensation.

Tumor.—Present and movable. Characteristic outline save where hydronephrosis has supervened as a result of frequent angulation of the ureter. May usually be traced to or replaced in renal region.

Impairment of function of intestinal canal.—None during attack. Disturbances of the large intestine, either diarrhea or constipation may form a part of the history.

Fever.—Negative.

CHRONIC APPENDICITIS.

Anamnesis, etc.—History of at least one preceding acute attack as a rule, with relapses. Rarely the clinical picture presents as a chronic condition from the commencement. This, however, may obtain in tubercular infection of the appendix.

Pain.—Referred to right iliac region betwen relapses.

Nausea and vomiting.—Not marked. Generally absent.

Tenderness.—Marked. Located at site of appendix.

Muscular tension.—Not marked.

Tumor.—Present. Immovable and usually located opposite middle of Poupart's ligament and attached to extreme right lateral lining of abdomen.

Impairment of function of intestinal canal.—Not marked.

Fever.—Fever not marked.

ABSCESS IN THE ABDOMINAL WALL.

Anamnesis, etc.—Is quite frequently of appendical origin, and therefore may give a corresponding history.

Pain.—Present. Strictly localized at the inflamed point.

Tenderness.—Localized. Greatest at most prominent part of tumor.

Nausea and vomiting.—Absent.

Muscular tension.—Not marked. Secondary induration may be mistaken for it.

Tumor.—Present. Fluctuating when sufficiently advanced. May be demonstrated in abdominal wall by lying patient prone and having him voluntarily lift occiput or feet from table.

Impairment of function of intestinal canal.—Absent.

Fever.—Present. Subject to remissions as in suppurative processes elsewhere.

IMPACTED URETERAL CALCULUS.

Anamnesis, etc.—Previous attacks referrable to nephrolithiasis, viz., lumbar distress aggravated by exercise; pus, blood and albumin in the urine; vesical irritability; pain in testicle, etc. Attacks of renal colic preceding the impaction and diminution of amount of urine excreted accompanying it.

Pain.—Dull, boring, intensified and becoming paroxysmal by spasmodic contractions of ureters. Radiates toward the groin and testicles, and sometimes to rectum.

Nausea and vomiting.—Not a frequent nor prominent symptom.

Tenderness.—Present, but not so definitely marked or fixed as in appendicitis.

Muscular tension.—Usually absent. When present, spasmodic.

Tumor.—Absent.

Impairment of function of intestinal canal.—None.

Fever.—Absent as a rule. At no time a marked symptom.

FECAL IMPACTION.

Anamnesis.—Follows most frequently a constipated habit and is observed oftenest in females and the aged. Favored by sedentary habits. May give a history of previous attacks. Hysteric and hypochondriacal, as well as spinal cord affections may form part of the history. Gradual onset.

Pain.—Not marked. Dull and obscure when present.

Vomiting.—Not a characteristic feature.

Tenderness.—Slight as compared with that of appendicitis.

Muscular tension.—Absent.

Tumor.—Presents itself as a doughy swelling.

Impairment of function of intestinal canal.—Constipation. Sometimes obstruction; but this rarely intractable.

Fever.—Absent.

TUBO-OVARIAN INFLAMMATION.

Anamnesis, etc.—History of menstrual disturbances usually of the too frequent type. Flow apt to become dark and clotted, thin leucorrheal, vaginal and muco-purulent discharge from endometritis. Symptoms gradual in their early development, but occasional acute exacerbations may simulate chronic relapsing appendicitis.

Pain.—Not severe, as a rule, save in acute relapses. With peritoneal involvement it may be sharp, but is constant, and not paroxysmal. Referred to iliac region, extending at times down the thigh and frequently accompanied by backache. Increased by over distension of bladder, distension of the intestines with gas; pressure and walking, riding or jarring aggravate it.

Nausea and vomiting.—Absent as a rule. Where present, accompanies supervention of an acute exacerbation.

Tenderness.—Not so marked as in acute appendicitis. More easily elicited by vaginal examination than external manipulation.

Muscular tension.—Absent.

Tumor.—The formation is an inflammatory mass. Conjoined manipulation maps it out distinctly and locates it in vaginal fornix. Uterus is pushed forward by mass. An exceptionally long appendix may give rise to a similar tumor.

Impairment of function of intestinal canal.—Constipation as a rule. This may be occasionally due to adhesions between adnexa and intestines. It is most apt to take place upon left side, the sigmoid flexure approximating more closely the left broad ligament. The appendiculo-ovarian ligament takes but little part in inflammatory attachments. Flatulence.

Fever.—Present in the relapses, and absent or nearly so in in the intervals.

CARCINOMA IN THE ILEOCECAL REGION.

Anamnesis, etc.—Symptoms come on slowly and increased by occurrence of constipation. Cancerous growths of bowel most frequently found in large intestine. Ten out of thirty-seven cases involved the cecum (Frank).

Pain.—Dull, with occasional exacerbations of lancinating pain.

Vomiting.—Absent.

Tenderness.—Usually spread over a larger area than in appendicitis.

Muscular tension.—Absent.

Tumor.—Hard, irregular, not of large size, and movable through a limited area. Not usually limited to cecum, but involves either ileum or colon.

Impairment of function of intestinal canal.—Obstruction to passage of intestinal contents when disease is advanced. One case of primary carcinoma of the appendix observed by the writer (see *Brooklyn Medical Journal*, April, 1897, p. 252).

Fever.—Absent.

RETRO-PERITONEAL SARCOMA PRESENTING IN THE RIGHT ILIAC FOSSA.

Anamnesis, etc.—Progressive loss of health and strength in youth or early adult life. Less frequently observed in those at or past middle life.

Pain.—Dull, aching, constant.

Vomiting.—Absent.

Tenderness.—Present; not distinctly defined or limited to point of invasion.

Muscular tension.—In advanced cases the corresponding thigh may be retracted from involvement of psoas muscle suggesting morbus coxarius.

Tumor.—Fixed, smooth and broadly definable.

Impairment of function of intestinal canal.—Absent.

Fever.—Absent.

DISCUSSION.

Dr. J. McFadden Gaston of Atlanta.—Some years ago I undertook to lay before this Association a paper upon the surgical lesions of the iliocecal region and it was upon such points which at that time were likely to attract attention. Dr. Fowler has brought forth a subject of great interest at this day. When we come to the bedside we have much difficulty in analyzing these points, especially in the case of families where one suspects appendicitis complicated with peritonitis. There are several points in connection with the troubles in this region that Dr. Fowler did not allude to. I had quite a puzzling case myself in this very line. The general symptoms simulated typhoid, but the local indications pointed to a local development of inflammation, and we thought of appendicitis. By temporizing, the case turned out to be one of typhoid. You have all seen cases of extreme sensitiveness in the iliocecal region in typhoid fever. There is sometimes also an inflammation of Brunner's glands which leads to the development of a tumor; and some of you have probably also met with cases in which you have had enteroptosis occurring in the ileocecal valve. I remember such a case in which death resulted in forty-eight hours. Even after death the grip of the valve was so tight that it would have torn it rather than give it up. In a simple case of contraction of the valve the intestine was readily liberated. There are other troubles that one can have at this point and it is important that we should study the matter up.

Dr. Howard A. Kelly of Baltimore.—I have been accustomed to pay close attention to this matter for some years and there are a number of diagnostic points which are very important and satisfactory. One can localize appendical inflammations in a woman and differentiate them from pelvic inflammations by paying attention to several points. In spite of the difficulties which may be maintained and demonstrated in most cases, there are cases of inflammation of the appendix and the right adnexa, probably 10 or 15 per cent. In one case reported in the Johns Hopkins Hospital Reports, a streptococcus inflammation was found in both the tubes and the appendix. I can hardly agree as to the propriety of removing the appendix, but I would rather get the meso appendix and lift it up over the pelvis. I know of three cases, like those the author has described, in which the appendix has become attached to a stump, and I operated on one case a year ago. One was also operated on by Dr. Hunter Robb and one by Dr.

Maguire. They found adherent appendices being pulled upon.

Dr. F. W. MCRAE of Atlanta, Ga.—In two of the cases I have had; the only symptom present for the first forty-eight hours was pain in the bladder, and in both cases there was retention of urine. The cases did not occur in my practice and the trouble with the appendices was not discovered for several days.

Dr. GARDNER of Rome—In reference to the class of cases of which Dr. McRae speaks I can report one. The patient was attacked suddenly with pain over the entire abdominal cavity. I saw him a few hours after the first attack and my diagnosis was a probable recurrent appendicitis, as he had had appendicitis one year before. The pain grew rapidly worse but was not altogether on the right side. The patient died in thirty-six hours and postmortem examination revealed the fact that an adhesion existed underneath the bladder.

Dr. FOWLER—In reply to Dr. Gaston, who stated that I did not mention typhoid, I would state that I came as near to it as I dared to, consistent with the title of my paper. There is a suppurative condition which occurs around the appendix giving rise to abscess, but all abscesses in the iliocecal region are not of appendical origin. I have knowledge of one case in which a perityphlitis formed about the site of an appendix, that had been removed. It was a case of secondary infection and the gut showed marked thickening. There was a history of impacted feces. The co-existence of ovarian and appendical disease is very important. Whenever I open the abdomen for appendical disease, and the inflammation is confined to the appendix, I carry my finger down into the pelvis and ascertain the condition of the adnexal organs. I have found in a good number of cases that a cirrhotic condition of the right ovary is frequently present as compared to the left. This is the case in that peculiar anatomic condition known as Clado's ligament, which is a peritoneal fold from the meso-appendix to the ovary itself. There is a constant irritation arising from this connection which will give rise to changes in the appendix. These inflammatory conditions, which evidently give rise to the cirrhotic condition of the ovary, may have their origin in the bacterium commune coli. As to receiving the appendix when you open the abdomen for other purposes, this is a question. If I thought its removal would add to the dangers of the patient I should prefer to let the patient take the chances of having appendicitis rather than remove it. In a typical excision of the appendix I use the thermo cautery so as to thoroughly sterilize the point of section, and with this precaution I believe it is safe to remove the appendix in any operation that you may do. The method which I employ takes no longer than does any other. Dr. Kelly's suggestion to elevate the appendix may be a good one, but he evidently overlooks the fact that this may imperil the integrity of an organ which already possesses but a low degree of vital resistance and in which inflammatory conditions may easily follow circulatory disturbances. The latter may be induced by the altered position of the meso-appendix which he brings about.

THE ETIOLOGY AND CLASSIFICATION OF TUMORS.

Presented to the Section on Surgery and Anatomy at the Forty-eighth Annual Meeting of the American Medical Association, at Philadelphia, Pa., June 1-4, 1897.

BY SAMUEL H. FRIEND, M.D.
MILWAUKEE, WIS.

A comparative histologic study of normal cells, those of all tumors and the two malignant growths, cancer and sarcoma, indicates some striking similarities and differences. These cells arising as they do from previously existing normal cells, this is not especially remarkable, though it is worthy of note. Enumerated these differences are: 1, a limiting membrane; 2, fibrillar; 3, protoplasmic; and 4, nuclear structure in all. In benign growths this varies in predominance according to structural origin; but in the two malignant growths there is: *a*, an increased thick limiting membrane in cancer and a normal one in sarcoma; *b*, an increased protoplasmic structure and nuclei in both, especially striking in cancer where the nuclei predominate. The study of the biology of these malignant tumors indicates this: 1, that they are rapidly growing cells; and 2, that this rapid growth is intimately associated with the predominance of nuclei in the cell. An examination of all of the different cells of the tissues of the normal organism gives but two sets of cells which bear a striking resemblance to these cells as to nuclei and protoplasmic structure present. These are the ovum and spermatozoa and the leucocytes of the blood. This similarity is suggestive. Tracing the origin of the leucocytes of the blood, from the work which the investigations of Ehrlich stimulated, and the zeal of Schwartze, Golasch, Fink, Gabriczewski, Müller, Reider, Neusser, Weiss Piorry, Boeckmann, Halla, Tumas, von- Jaksch, von Limbeck,[1] Pée, Goldscheider, Jakob and many others roused, all indicate that these leucocytes are, 1, locally increased whenever any cause determines blood to a part; and 2, generally increased in all digestive processes, in diseases of the blood-making organs and in most acute febrile and in many chronic conditions, irrespective of the organ or organs diseased. Cohnheim[2] first advanced these theories, Neusser[3] further advanced them and Weiss[4] directly suggested them. The leucocytes are produced by any and all tissues of the organism. The inductions of Cohnheim, Neusser and Weiss, taken with the following, indicate the truth of such an interpretation and its application to pathologic phenomena.

As first observed by John Hunter and as others have confirmed, there is an increased number of leucocytes at the seat of a cut. I will simply draw the attention to this phenomenon as occurring not only in all traumatisms but, as above stated, in all normal functional action and conditions where there is a sudden or a prolonged determination of organic, inorganic, mechanical, electric and chemic action and matter to a part. As to the place of the leucocytes in physiologic activity and in the healing processes, details are unnecessary. Though their origin in traumatisms has been determined, yet a recapitulation may prove suggestive. If a cell or cells of the skin or muscle be cut or bruised, or if it be stimulated beyond a definite range, the immediate effect is to determine excessive blood containing excessive leucocytes to the parts and to stimulate the entire cell. So it not only attempts but does rapidly reproduce itself. While in a normal condition of the organism the phenomenon of cell division is produced within a definite range of time, by karyokinesis in an abnormal state, as in traumatisms, etc., the phenomenon is hastened and, as a result, borne out by investigation, the normal cell stimulated and, as if to compensate for the new environment of the tissues, reproduces itself not only by normal but also abnormal karyokinesis, and likewise by simple division and gemmation. A cut, a bite of the skin, etc., irrespective of the structural or functional agent, affects the true skin, all of the cells[5] which make it up as an organ and the entire organism. Locally the structure of the blood vessels, blood, lymphatics, hair and sweat follicles, muscles, etc., have their reproducing powers augmented as enumerated, and the result is an innumerable number of new cells having the characteristics of leucocytes. An investigation of the blood demonstrates that these cells and those brought to the parts are thrown in and about the wound, and that some leucocytes, more than normal, independently find their way into the blood by their very motion. The fact that infection progresses and becomes general or special either through the agency of the leucocytes containing the organism or by their being independently carried into the blood vessels or lymphatics, proves the same truth. That under the same and different conditions these processes also occur within the organism, seems a natural inference.

Studying micro-organic diseases, especially when some lesion exists, one of the first observations made either in an examination of the blood and of the tissues involved, is an increased number of cells and leucocytes in the parts. As has been observed, first by Virchow in his observations of the tissues surrounding a new growth, as described in tubercular processes, and more recently noted by Metschnikoff in the struggle of the phagocytes, the leucocytes are the natural protectors of surrounding normal tissue. Again, in the blood of those having cancer or sarcoma, as investigated by Velpeau, Breard, Bouillaud, Broca, Jollin, Cruveilhier, Paget, Lücke, Andral, Gavaret, Hayem, Palma, Rieder and many others, a leucocytosis is the rule. To detail all the conditions where this phenomenon is observed is unnecessary, for the entire phenomenon can be included in the following: All organic structure and function, chemicals whether organic or inorganic, mechanical, thermal, electric contact, in the organism and organic chemicals by excessive activity, numbers and quantity, in the mechanical, thermal and electric processes by direct excessive contact, can produce an excessive cell reproduction. The process of this is that excessive quantities of blood and leucocytes are determined to the parts and furnish excessive nutrition to the overstimulated cells. A study of all normal tissues indicates that each and all have a definite, constant number and arrangement of cells. Diseased tissue indicates the contrary, that is, an indefinite number and partial disarrangement of the structure and function of the cells. Taking the histology of cancer or sarcoma as an illustration, these growths are types of both, the normal arrangement persisting being the general structure of cell which adheres to that of hereditary mother cells. Going back to the above generalization in regard to the stimulus of cell reproduction, and as Roux[6] intimated, in localized abnormal cell reproduction, as in all natural phenomena, there is a struggle made by all cells of organs and tissues to retain their original form, size, arrangement, function, numbers, etc. Applying this to the above and to all blood studies, the indication is that all overproductions, 1, either find their way into the blood or, 2, if retained in a part, become starved and starve the fixed cells or, 3, are consumed and furnish extra nutrition or, 4, become infected and die or, 5, there is a localized overgrowth, and in these ways the cells of tissues of organs and systems attempt to protect themselves, the organ and the entire organism from an overgrowth. When a certain number is reached in the blood, the normal process appears to be that the liver and other organs destroy the overproduction. As understood, each cell of each organ and tissue has a normal overproduction of cells and supplies a certain number to the blood, and of the entire organism, a constant number persists in the blood. An organ or structural part of an organ becoming diseased does one of many things: It either increases or diminishes both function of the organ and tissue, and that of the entire organism. To illustrate: In typhoid fever the digestive processes are inhibited; in tuberculosis of the lungs the respiration action is inhibited; in meningitis the nerve function is increased, etc. Varying with these inhibitions and excitations there can be observed concomitant inhibition and excitation of other functions. In some conditions one or more functions are excited, others inhibited. As can be observed in some cases of tuberculosis, while the rule is for a leucocytosis to exist, yet in some cases a leukopenie occurs. This evidence demonstrates the interdependency of the entire organism. In localized functional and structural disease this evidence would seem to indicate that where the normal range in numbers of leucocytes does not occur in the blood and is not compensated for, the production or the overplus reproduction of the cell of the entire organism is inhibited, and that the overproduction of cells in the diseased tissue is retained within that area. As is indicated by giant cells and the ring of granulation tissue limiting tuberculous processes, this evidence would suggest, as first observed by Virchow, that this ring of cells was present to protect the tissue of the entire organism from infection. As understood at the present time, this is not only true but, as first suggested by Metschnikoff, the cells of this tissue attempt to destroy the organisms present. We have learned that not only cells and minute organisms and their chemic products excite cell reproduction, but likewise many chemicals, as the alkaloids, acids, salts, thermal agents as heat and cold, electricity and mechanical pressures, as observed by Hirt, H. Meyer, Pohl, Binz, Löwit, Goldscheider, Jakob, Winternitz and many others. These facts are demonstrated by direct clinical and experimental observation. It will hardly seem necessary to go into the minute details of the increased production or different kinds of cells[7] in all normal and abnormal phenomena. The only limitation is the cells of the different tissues. Yet, upon observing the abnormal production externally, irrespective of its cause, and knowing that the same process and phenomenon must occur internally, one asks, when they have neither external nor internal outlet nor compensate for some pathogenic process, what becomes of the cells? Studying the blood of those having external wounds, structural diseases of different organs, internal and external new growths, we find that while there is an increased number of loose cells about the parts, there is also an increase of leucocytes in the blood. All of this evidence with that of those mentioned demonstrates, from the similarity of the cells produced to the leucocytes of the blood, that, as Weiss concludes, their relationship is not a coincidence, but they are the same cells. This conclusion brings to the etiology of new growths an entirely new interpretation and to our knowledge much light.

Reasoning now as we can upon biologic,[8] embryologic,[9] comparative anatomic,[10] pathologic,[11] physiologic[12] and clinical evidence,[13] that knowledge combines to indicate that we can typify the structure and function of the organism of man as a single cell. This is indicated by the integumentary system corresponding to the limiting structure and function; the osseous system corresponding to the fibrillar structure and function; the muscular, nervous, blood vessel, digestive, excretory and secretory system corresponding to the protoplasmic structure and function; the ovaries and testicle corresponding to the nuclear structure and function. As the entire organism can be so typified, so can each system, organ and cell or combination of cells making an organ and system. All detailed studies demonstrate this and also that the integumentary structures and function of man is an evolution of the limiting membrane of lower organisms. It has passed through and represents the different stages, namely: 1. Chitinous cells, fibrous, calcareous, scales, horn, feathers, hair, with the evolution and specialization of the present limiting membrane structure with its epidermal specialization; 2, a fibrillar network beginning with fibrous, elastic, fibro-elastic, calcareous and being gradually specialized to represent all structure with the evolution and specialization of an osseous system as represented in man; 3, a protoplasmic structure ranging from the complex structure within the limiting membrane and fibrillar structure, as indicated in the lowest organisms, to the evolution of the specialization of digestive, vascular, secretive, excretive, muscular, sensory and motor nervous structure of man;[4] a nucleus being a part of the whole structure, as indicated by the function of gemmation and division in lower organisms. Then arises an evolution of the nucleus. Though it be retained in every cell of the organism it ranges gradually to the evolution of the complex structure and function as indicated in the ovaries, uterus, vagina, testicles and penis of man.

Functionally it can be observed that each part of this structure has a definite range of action. Studying this comparatively it can be observed that this limiting membrane protects the three internal structures from these external natural and artificial environments: Atmospheric, liquid and solid pressure, heat and cold of gases, liquids and solids, electricity, chemical affinity, cohesion, adhesion, the attacks of other animals. This analyzed indicates, as is absolutely known, that variations of all of these forces exist and have a definite action on the organism. Applying this interpretation to man it can be observed that the limiting membrane directly and the other structures indirectly have, besides these natural forces, an environment subject to known action within definite limits, known and applied by man, evolved by him, organized by limitation. By this new environment man is made capable of accommodation irrespective of the natural environment. This makes an artificial environment, which though distinct is so intimately associated with the natural environment that it is of difficult discrimination in its activity. Yet it has likewise a definite direct action upon the action of the entire structure.

Studying again, comparatively, the functional action of the external environment on the protoplasmic, fibrillar and nuclear structure, it can be observed that this functional action has also a direct connection or communication as indicated by the gases, liquids and solids absorbed. These in turn, while producing direct action of the three named structures, also produce an indirect action on the entire structure. Analyzing the matters absorbed by lower organisms, making a direct and indirect internal environment we find them to be gases, liquids and solids, both inorganic and organic, producing direct functions and persistence of all the structures. Applying this again to man we find the same with the difference that gases, liquids and solids absorbed are artificially prepared, and that as a result of the aggregation of man and the consequent organization of communities and cities these matters are contaminated. The result is still further contamination owing to this artificial preparation and contamination. This result is due: 1, to matters excreted, and 2, by increase of the range of forces necessary to convert these matters to the complex simplicity of matters for the requirements of persistence of all divisions of structure.

Studying comparatively the action of lower organisms and man, we find that in the former this is confined to motion, absorption, secretion, excretion and reproduction, that is, the action of primary instincts. Following each function we find that this is gradually augmented until the complex instinctive and conscious activity of man is reached. Here can be observed the specialization and effects of the control of instincts, conscious control of nature's forces, the limitation of the activities of lower animals and for the specialization and vocation of man for necessities of persistence in time and space, the use of inorganic and organic matter. As all investigations indicate, man's original environment was tropical and subtropical. He collected in varying numbers over large spaces of land and his functional activities were confined to absorption, secretion, excretion, reproduction and excessive motion in quest of foodstuffs and preservation of life against enemies. Studying man as affected by a changing environment and comparing this with his present activities the following as mentioned is demonstrated: That he has augmented and modified through the instinctive recognition of the laws of the survival of the fittest, compensation and accommodation, both the natural environment and himself; and as a result in the building of cities, etc., he has made an artificial environment. Through the application of the laws of the forces of nature's phenomena, by these forces he has also increased the activities of producing a survival and persistence of self by making vocations which through training specialize the special senses and entire organism and which have a value for sustenance and survival. This is dependent on supply and demand and an interchange.

The artificial environment evolved has been the shelter of clothing and house and the use of prepared foods, the former two compensating the variations in atmospheric temperature and pressure, etc., and all used in functional activity. The first, clothing, has developed from the use of skins, pelts, etc., to the gradual employment of the limiting membrane of animals, their larvæ and vegetable matter which are prepared by man—an exchange of his labor or action for other necessities—these materials to compensate for variations of temperature, etc., are made into clothing for body, foot and headwear. The second, house, has been evolved from caves, the use of skins, branches of trees, grasses, earth, to the gradual use of logs, stones, the manufacture of bricks, etc. Thence the evolution proceeds to the present heterogenous matter combining all and compensating not only for variations in temperature, but likewise for protection against storms of wind, water, hail, snow, etc.

The third, food, has been evolved from the use of unprepared animals, vegetables, to the evolution of the preparation and preservation of both and the concentration of some as sugar, salt, fats, etc. These concentrations compensate for the renewal of structural matters used in man's functional activities. Man is then a natural cell and an artificial organism. As a natural cell he has the activities of motion, absorption, secretion, excretion and reproduction. As an artificial organism he has acquired compensatory shelter of clothing, house and preparation of foodstuffs. *These are produced by him through the specialization of all of his activities.* The effect of the compensations is to produce activities of parts and the whole structure not normally, hereditarily developed. As can be observed the newly born infant is almost immediately tightly clothed, and as a rule in this country fed with artificial foodstuffs. Even in earliest infancy either the one or the other or both produce skin or limiting membrane eruptions. Take again in later childhood, there can be observed the development of various structural changes as could be endlessly enumerated. These changes produced directly on those using and making artifices occur in the infant, child, youth and adult. The process is, that active and passive structural parts and normally retrograding structure are abnormally stimulated in a range out of harmony with normal structural and functional possibilities. As a result overgrowths are produced. As is borne out by pathologic investigation these overgrowths can be classified naturally under four original typical, structural and functional biologic divisions, namely: 1. Limiting membrane; 2, fibrillar; 3, protoplasmic and 4,. nuclear with the various combinations as observed clinically, anatomically and histologically as follows:

1. Excessive growths or tumors of the limiting membrane typified by clavus, cornu cutaneum, etc.
2. Excessive growths or tumors of the fibrillar structure typified by fibroma, chondroma, osteoma, etc.
3. Excessive growths or tumors of the protoplasmic structure typified by myxoma, myoma, lipoma, neuroma.
4. Excessive growths or tumors of the nucleus typified by sarcoma and cancer.

As microscopic evidence indicates these pathologic overgrowths, give the following mixtures either alone or in combination, making the following subgroups:

a. Excessive limiting membrane with diminished fibrillar, intraprotoplasmic structure and nucleus, typified by dermoids.

b. Excessive fibrillar with diminished protoplasmic, limiting membrane and nucleus, typified by fibroma, osteoma, chondroma.

c. Excessive protoplasmic structure with diminished nucleus, fibrillar and limiting membrane structure typified by lipoma.

d. Excessive nucleus with diminished protoplasmic and fibrillar and limiting membrane structure, typified by sarcoma of special organs and tissues.

e. Diminished limiting membrane with excessive fibrillar, protoplasmic structure and nucleus, typified by cancer or sarcoma of special organs and tissues

f. Diminished fibrillar with excessive limiting membrane, protoplasmic structure and nucleus typified by papilloma.

g. Diminished protoplasmic structure with excesive limiting membrane, fibrillar structure and nucleus typified by cancer or sarcoma of special organs or systems as the lip, tongue, etc.

h. Diminished nucleus with excessive limiting membrane,fibrillar and protoplasmic structure, typified by angioma.

i. Absent limiting membrane with excessive or diminished fibrillar, protoplasmic structure and nucleus typified by polypi.

j. Absent interfibrillar with excessive or diminished limiting membrane. protoplasmic structure and nucleus typified by adenoma.

k. Absent protoplasmic structure with excessive or diminished limiting membrane, fibrillar structure and nucleus as typified by cystic tumors. The processes and effects of all of these are determined by the laws of the survival of the fittest, compensation and accommodation. This functional action determines excessive cell division and blood to the parts containing excessive nutrition held in solution and in the leucocytes. Both of these give one of the four parts of the structures represented in every system, organ and cell an advantage in predominance.

Studying their clinical histories we find that while the origin of some tumors in certain places can not be defined, yet the same growths in other places give a definite etiology. Reasoning as we can that all organs, systems and cells have represented all four structural parts as a result, it is made possible to apply the logic of that history to the growths hidden to the naked eye. I speak of intra-abdominal, thoracic and cephalic growths. As is indicated by external tumors whether they be benign or malignant, all growths have a definite cause. As already stated it can be demonstrated that all cell division can be excited or increased in time by organisms. It matters not if the organisms are excited by cells of tissue pathogenic organisms; by chemicals of both organic and inorganic matter, which includes the products of micro-organisms; by mechanical, thermal and electric applications. This cell division is further demonstrated by physiologic and embryologic evidence which indicates the excitation of the reproduction of all structural divisions of organic cells. This can be seen in the impregnated ovum, which not only is itself stimulated, but likewise stimulates an excessive motion, absorption, secretion, excretion, reproduction, etc., of all structural divisions of itself and the organ or tissues in which it lodges. The uterus in normal pregnancy and the Fallopian tubes in extra-uterine pregnancy indicate the same things.

Physiologic and experimental evidence also indicates how cell reproduction of protoplasmic structure is stimulated in functional excess as in specializing systems and organs, as the muscular, digestive systems, etc., seen in athletes, gourmands, etc.

Biologic, pathologic, clinical and experimental evidence indicates such excitation of all structural division of the cells or minute cell organisms by pathogenic organisms. This appears in tubercular processes, etc., and as is indicated by clinical and experimental evidence, the same excitation occurs through contact with organic and inorganic matter by chemicals, mechanical pressure, heat, cold and electricity, organic cells in excess, bacilli and micrococci, acids, ptomains, alkalies, excessive pressure of clothing, etc., excessive heat and excessive cold, then heat, and lastly through galvanic electricity.

As pathologic evidence of the pure mechanical excitation of the reproduction of protoplasmic and nuclear structure, we know that epithelioma of the lip may be caused by pressure. In embryologic excitation we have dermoids, which indicate the persistent determination of excessive nutrition to a part by either rests and vestiges of congenital significance. A periodic wandering and retention of fixed cells likewise observed in metastasis indicates the same determination. We know that sarcoma or nuclear excitation of bone structure may be produced by excessive pressure, as by excessive lying upon a firm hard matter such as a hard board table. Here the great trochanter undergoes too much pressure and consequently excites excessive division and leucocytes to the parts and compels a too rapid and perverted cell division. In clavus, fibroma and myoma, etc., the same logic of either organic, inorganic, chemic, mechanical excess, etc., will hold good save that in these cases the rapidly dividing cell which matures represents equally one of the structural parts of the cells of its original tissue. This is probably caused by a normal mitosis, the quality of the stimulus and the nutrition coming to the parts. This pathologic evidence indicates that irrespective of the location of the overgrowths the same etiologic application of excessive cell reproduction, etc., obtains. An analysis of the cell of cancer and sarcoma indicates, as already mentioned, that both represent structurally and functionally a predominance of protoplasmic and nuclear structure, their discriminating difference being in the limiting membranes. The former is said to have its origin in epithelial, the latter in connective tissue cells. From the above interpretation of the entire organism this division is quite irrelevant, as boths cells practically represent a predominance of the same structural divisions of the cell, namely, protoplasmic and nuclear structures. As these structures exist in all cells of all tissues these two growths can be found in any tissue of the entire organism.

Studying the microscopic and macroscopic area of both cancer and sarcoma we find that they have a definite and constant physiognomy. Detailed this picture shows in cancer first an overgrowth of the distinctive cell and a compensatory growth as if to limit the extension of the growth of these cells, of the connective or fibrillar cells. In sarcoma the growth is of the same cells without any attempt at compensatory hyperplastic, morphologic limit of surrounding cells caused by a too rapid formation of the cells. Yet a close study shows the great similarity as detailed, but while both cells grow rapidly in sarcoma the cells develop so rapidly that the impressed phenomena of cohesion, adhesion, etc., have a diminished force. It is needless to remark after carefully detailing the organization of the two structures that their similarity is striking and their etiology is suggested to be the same. Studying these suggestions physiologically, clinically and histologically, and from the comparative points of view, they demonstrate that these overgrowths are caused by a predominant stimulus to the nucleus of the cell in a range not in harmony with functional requirements or with the development of the mature cell from which they originate. The presence of a perverted mitosis demonstrates microscopically its biology. This stimulus is either long continued or persistent, periodic, organic, chemic of both inorganic and organic matter; mechanical either long continued, persistent, periodic excess, as pressure, heat, cold or electric application with a concomitant excess of the absorption of cells rich in chromophilic matter. If now we recall the origin and cause of the rise and fall of the leucocytes in the blood we have demonstrations of their sources and kind; the effect of their retention and excessive numbers. As already stated, as suggested by Cohnheim, Neusser, Weiss, and as is indicated by all clinical evidence, by the effect observed microscopically in the immediate effect in the healing process of cuts and bruises, the leucocytes of the blood are an overproduction of cells of all the different tissues. Some of these tissues are richer in nuclear and other matter than others. The question then comes what becomes of these cells when they are predominantly retained within the tissues? As is indicated by pathologic evidence we have atrophies, hypertrophies, hyperplasias and tumors as final structural disease effects. All are caused by structural and functional excess. Reasoning from these premises the mechanism of structural and functional organic and inorganic, chemic, mechanical, thermal and electric action upon the cells of tissues is to produce an excessive determination of blood to the parts. This mechanism also produces an excessive motion, absorption, secretion, excretion and division of the cells of the part and of the cells of the entire organism, consequently of the leucocytes brought to the parts. As is indicated in traumatisms this demonstrates that more converted and to be converted nutrition comes to the part than is normal. If this overproduction is not compensated for by being taken into the general circulation, etc., there is then produced, as pathologic evidence demonstrates, either atrophy, hypertrophy, hyperplasia or tumor. As observation and experimentation indicates and pathology demonstrates, the application of the above to these four structural changes, is as follows: When a retention of these overproduced cells occurs, a time will occur when they will produce an excessive: 1. Reproduction; 2, absorption; 3, excretion; 4, secretion; 5, motion, which in turn will react upon each cell exciting a further cell division. The effect of this must then be to excite either all the cells of the different divisions of the tissues of the part or of a single tissue or division of tissues, when there will be an overgrowth of all or one or two, or three, or four structural divisions of the cell of the tissue.

Studying the histology of an atrophic cell we find that the nuclear and protoplasmic structure is predominated by fibrillar and limiting membrane structures with a change of form and size of cell, and chemically a change in the secretion and excretion. The interpretation of this implies that the overproduction of cells have become starved and in turn have starved the fixed cells and compelled a lower structural organization. The scar cells especially show this. The scars produce before antiseptic surgery was known emphasize this. The small hemorrhages in the brain and spinal cord producing the well-known sclerosis also show this. The process and effect of all this is determined by the predominant action of the law of accommodation.

If not atrophy but hypertrophy occurs, then the contrary can be observed. All structural parts of the cell become equally enlarged and with the all there is an abnormal function. This indicates that the structural and functional increase is simply compensatory and in harmony with requirements, the increased soluble nutrition and leucocytes furnishing the necessary matter. The process and effect of all this is determined by the predominant action of the laws of accommodation and compensation.

If again such an abnormal activity exists and neither atrophy nor hypertrophy occur, but a hyperplasia, then the interpretation is: That the matters absorbed have contained pathogenic organisms or that man has had external contact with them. These lodge: 1, in a fixed cell, and excite excessive activity, or 2, are carried to a distant division of the organism either in the blood current or, 3, are taken up and so transported by leucocytes already existing in the blood and ultimately lodged in a fixed cell. In this fixed cell, in the struggle which occurs, all activities are increased. This struggle not only calls for and receives extra nutrition, but stimulates all of the cells surrounding the parts, as is demonstrated by all pathogenic symptoms and microscopic investigation of typhoid fever, tuberculosis, etc., and all kinds of septic wounds. As is indicated in the healing processes, these abnormally stimulated cells are of two kinds, viz.: auxiliary or vanishing, and fixed cells, the first being the wandering leucocytes, which as above detailed are normally compensating and protecting. They have predominating protoplasmic and nuclear structure and as compensatory function an excessive motion, absorption, secretion, excretion and reproduction. The structure and function can be demonstrated histologically and chemically by the tissues and the blood. The presence of fixed cells is indicated by the healing process. This demonstrates that some of the excited and rapidly dividing, absorbing, etc., cells persistently grow and develop compensatory structure and function of original mother cell, and in this way produce compensatory regeneration by producing a cell as detailed in atrophy. Applying the laws of biologic phenomena to this process and effect, the indication is that the laws of the survival of the fittest and accommodation have a predominant action.

If instead of atrophy, hypertrophy or hyperplasia, an overgrowth occurs, the indication is that the causes as mentioned produce and persistently determine an excess of the leucocytes and the fixed cells. This interpreted indicates the following simultaneous phenomena: Excessive motion, absorption, secretion, excretion, perverted mitosis of fixed cell of part, in the two malignant overgrowths. There is also excessive determination of blood to the parts together with its excess of converted nutrition held in solution and an excess in number of leucocytes coming from tissues (apply Weiss' conclusions), leucocytes structurally rich in nuclear and protoplasmic matter. Besides having their activities augmented these leucocytes are consumed by the fixed cells and furnish extra nutrition. This makes a definite reinforced mechanism dependent upon the persistence of the original cause amplified by biologic activities. Applying the laws of biologic phenomena to this process and effect. the indication is that the laws of the survival of the fittest, compensation and accommodation predominate.

X-RAYS AND X-RAY DIAGNOSIS.

Read before the California State Medical Society, April 20, 1897.

BY PHILIP MILLS JONES, M.D.
CHIEF OF THE DEPARTMENT OF ELECTRICITY, UNIVERSITY CALIFORNIA.
SAN FRANCISCO, CAL.

A great discovery, great in the sense of discovering a fundamental principle or a fact profoundly modifying existing theories or hypotheses, is not infrequently found to be of most value, from the purely utilitarian standpoint, in some branch of science, or some art, other than that in which it was primarily made. One of the most striking examples of this statement is to be found in the history of what has become bacteriology. Pasteur was seeking for the cause of fermentation, and more particularly the fermentation of grape juice: yet his discovery has revolutionized the practice of surgery and almost transformed the practice of medicine.

Admitting that science and many of the useful arts have profited largely by the discovery of Pasteur and the researches of subsequent investigators the fact remains, and I think will not be disputed, that society has been most benefited through the influence of the discovery and its developments upon medicine and surgery. Many other discoveries exhibit the same fact though hardly so clearly and typically as the one cited.

Very recently we have been furnished an illustration in the discovery of a new form of radiation made by Professor Roentgen in December, 1895, and announced by him at Wurtzburg in January, 1896. The researches of Roentgen were no more due to a desire to advance the practice of medicine than were the researches of Pasteur; the one was investigating certain physical phenomena in the domain of pure science; the other was investigating the cause of certain processes in a commercial industry, the production of wine. But as with the discovery of the yeast fungus, so with the discovery of the X-ray the principal benefit has accrued to medicine. I therefore deem myself justified in considering "X-rays and X-ray diagnosis" as eminently a subject in medicine.

A detailed and connected account of the steps in the process which led up to the discovery by Professor Roentgen of this form of radiation, unknown and unsuspected, would mean a careful review of the work of Galvani, Faraday, Coulomb, Thompson, Geissler, Crookes, Hitthoff and Leonard, to say nothing of many other and less widely known investigators. Coulomb and others studied carefully the inductive capacity of dielectrics, and naturally gases at various pressures were included. From a study of inductive capacity, it was but a step to the observation of disruptive discharge, and Geissler made the first notable advance in regard to discharge through gas at lower than atmospheric pressure.

In Geissler's experiments polarity first assumed an important position as presenting certain different and interesting phenomena, depending upon the direction of current flow; Crookes and Hitthoff, by virtue of improved apparatus enabling them to obtain higher degrees of vacuum, were able to more accurately differentiate the phenomena exhibited at the kathode and anode poles during discharge in vacuo. Crookes particularly was impressed with the anomalous character of the phenomena exhibited at or by the kathode terminal during discharge in a vacuum, and was led to suggest a fourth state of matter, being otherwise unable to explain the conditions found. This announcement and his experiments, which were exhaustive, naturally evoked much interest and criticism among scientists. Philip Leonard commenced investigating the subject with the result that he was very soon able to obtain much more curious manifestations of kathode discharge—he demonstrated the possibility of detecting the presence of rays, which he assumed to be kathode rays, outside of the vacuum in which they were produced. These many discoveries attracted the attention of numerous scientists, among whom was Professor Roentgen, and it was while studying the phenomena recounted by Crookes, Hitthoff and Leonard, that he observed another form of radiant energy emanating from the vacuum tube, a form of radiation apparently different from any previc [illegible] oted; for while light and kindred rays could [illegible] d, reflected and refracted, and kathode and Leonard rays could be deflected by a magnet, the rays observed by Roentgen were not subject to reflection, refraction or magnetic deflection. Hence as they were unknown he called them "X." This X radiation, merely another discovery in pure science, has become one of the most if not indeed the most valuable aid in the diagnosis of a large majority of surgical cases, and this within little more than a year. Its present value if only in presenting bone lesions and foreign bodies to the visual examination of the surgeon will hardly be denied by any competent observer, and its possibilities can not be prophesied.

So much interest has been evoked by the possibility of "seeing one's own bones," that a great deal of kindergarten investigation has been done, and too often conjecture and speculation have assumed the rightful places of scientific observation and cool-headed deduction; opinions have been asserted as facts by men who unquestionably should know better. With no discovery within my recollection has the immediate and general excitement been so intense, or the subsequent deluge of absurd and improbable statements so great as with this discovery of Professor Roentgen.

The requisite conditions for the production of X-rays are essentially, first, an apparatus capable of producing a difference of electrical potential sufficient to produce a spark in air of three or more inches, and second, a non-conducting vessel of some material penetrable by X-rays, and in which a vacuum of three mm. or less may be maintained—this ordinarily takes the form of a glass tube or bulb, with one or more platinum wires sealed into the glass terminating within the tube in a variety of shapes. It is not essential but it is desirable that the terminal to which it is intended to attach the leading-out wire (the kathode terminal) be made of aluminum, except the portions making the glass seal and external to the tube. The anode terminal may be of any conducting material, preferably platinum. When an excessively high potential current is used, one terminal only need be made in the tube, but the generally available apparatus necessitates the operation of the tube on a closed circuit of which it is itself a part, and hence the tube must be provided with two or more terminals. A large number of tubes of different materials, shapes, sizes and arrangements have been made and experimented with; and the question of the material, size and relative position of the terminals has been carefully studied, the consensus of opinion being that for the production of X-rays of high penetration and in considerable volume, the tube must be of German or lime glass, generally spherical, and the kathode terminal of aluminum in the shape of concavo-convex disk, the concave surface being directed inward and the curve and position such as to bring the kathode rays to a focus upon the platinum disk in which the anode terminates. The anode disk should be inclined at an angle of about 135 degrees from the kathode. This style of tube, now generally called the focus tube, I concluded from my early experiments would be most satisfactory, and subsequent trial demonstrated the value of my conclusions. . I was not alone in the discovery, for a few days after I had my first focus tube made I received a description of a form of tube precisely similar which had been designed by a professor at Kings College, London. Several times I have made discoveries which in a short time I found had been independently made by other investigators.

The high tension current for exciting the tube may be obtained in a variety of ways which are divisible into three general types, *i. e.*, the induction or Rhumkoff coil, the high tension alternating current transformer or "Tesla coil" and the friction or influence machine.

In the induction or Rhumkoff coil, the high voltage is produced by breaking a direct current circuit in a primary of few turns of large-size wire wound about a soft-iron core, the high tension current being induced in a secondary winding consisting of many turns of fine wire insulated from the primary coils. There is a certain amount of current induced in the secondary upon making or closing the primary circuit, but as it is the result of electric induction only, it is very small in comparison with the current made by breaking the primary circuit, the high voltage in the latter case being the result of the electric induction plus the magnetic induction of the soft-iron core. When a high resistance is introduced into the secondary circuit, the current in that circuit produced on closing the primary circuit becomes negligible and the effective voltage may be regarded as unidirectional. Coils of this type have been constructed to give a spark in air forty-two inches long. I have made a number of such coils of various sizes, using different wire for the secondary winding.

The high frequency high potential alternating current transformer, sometimes called "Tesla coil," offers a very inviting field for the experimenter. The apparatus consists essentially of some source of E.M.F., which may be made to charge condensers, the latter being disruptively discharged into the primary circuit of the coil immersed in oil and consisting of a primary and secondary coil, each being of comparatively few turns of wire, the secondary, however, having more turns than the primary; the resultant high potential current is produced by electric induction and is an alternating current.

The influence machine is sufficiently well known to need no description and may be constructed to produce very high differences of potential and a current either direct or alternating. To produce the best effects from either the Tesla apparatus or the static machine a very careful adjustment and balancing of the apparatus is essential; therefore, when the apparatus is intended solely for the production of X-rays, the direct current coil is preferable to either of the other devices as being more easily, uniformly and satisfactorily operated. I have experimented with all three of these forms, but for actual diagnostic work employ only the induction coil.

In physics, not a great deal more is known now than was contained in Professor Roentgen's orginal paper. I early found the X-rays to emanate from two or more points in the tube, the anode terminal and the area bombarded by the cathode stream. I also made several experiments to ascertain the law of absorption of these rays and found that the metals increase in absorptive power with increasing atomic weight; the salts of the same metals may be arranged with reference to their absorptive power in an increasing series as follows: carbonate<nitrate<sulphate<chlorid<bromid<iodid.

Several theories are current as to the nature of these rays; some investigators deem them longitudinal ether vibrations, others regard them as streams of projected particles; the majority of physicists, however, are of opinion that in this phenomenon we have only another electro-magnetic wave, an ultra violet wave of very short wave length, probably about three octaves above the shortest previously known ultra-violet waves. Certainly the X-rays are non-homogeneous, for several quite different series of phenomena may be observed, produced by them. I myself demonstrated either four distinct forms of X-rays, or else rays of four different wave lengths, almost a year ago. The dermatitis Roentgenii, which will be subsequently mentioned, seems to have some relation to this question of non-homogeneity of the radiations from the vacuum tube, indifferently called "X."

The application of X-rays in medicine has thus far been confined almost entirely to surgical diagnosis; a few instances are recorded where they have been therapeutically employed, or rather empirically employed, in the treatment of tuberculosis pulmonalis, with, in some cases, apparently good results. Whether the benefit in these cases was, however, to be assigned to the action of the rays *per se*, or to the counter-irritation produced by extensive dermatitis R., remains an open question.

The list of foreign bodies that have been accurately located by means of the X-rays is a very large one and includes the greatest diversity of objects and covers almost the entire body. I have personally located and by that means enabled the operator to easily remove needles and pieces of glass from the hands and feet, and bullets from various parts of the body, including the second lumbar vertebra, and a hypodermic needle in the thorax. As most of the foreign bodies with which we have to deal are metallic, and as the coefficient of absorption is greater for the metals than for any of the salts of the metals or any organic substances, the foreign body usually intercepts many more of the rays than the surrounding medium and consequently casts a more dense shadow.

Fractures and dislocations, though usually easy of diagnosis, are sometimes very puzzling, especially when near joints and when some time has elapsed after the injury and the soft parts are much swollen. No matter what the natural ability, education or experience of the fingers they may often be at fault; here, however, we have an agent that can not err; if it give an answer at all, it must be truthful and must show to the examiner the actual conditions. The fractures and dislocations that have been examined with much profit by this means includes almost every large bone, almost every joint in the body, and no man who has availed himself of this aid in such cases will speak of it in any terms save those of highest praise.

Certain diseases of bone are also diagnosable by means of these rays, owing to the difference in absorption existing between the diseased bone and normal healthy bone. Exostoses intercept a number of rays equal to the number absorbed by the same quantity of similar normal bone, and hence are diagnosed by comparison with a skiagraph of the same region showing the normal anatomic outline and relations. In necrosis and tuberculosis, however, the conditions are different and diagnosis permitted, owing to the coefficient of absorption of the rays being not constant for both healthy and diseased bone.

Some hard tumors situated in the soft parts may be located and examined to a certain extent; any attempt at differential diagnosis can not be made in these cases, however, until sufficient material has been collected on which to found opinion by contrast and experience. It seems quite possible that the rays may eventually be found to possess some value in this direction.

The X-rays furnish a most satisfactory means of examining the chest for various purposes. The heart can be very readily seen in outline, and the facts relative to its size, exact location and movements noted at once. Sight is a much more satisfactory agent of information than hearing or touch, and consequently the opinion derived from a visual examination is much more decided than that obtained by percussion or ascultation. Aneurysm of the aorta is frequently seen in shadow, though it may exist and, if small, not be detected by this means. Areas of solidification in the lungs cast shadows more dense than the surrounding lung tissue and are hence detected and exactly outlined; any change in their size or density may be noted, too, by repeated examinations.

The abdomen has thus far proved to be a less fruitful field of investigation; the liver, kidneys and occasionally the spleen may be outlined fairly well, and calculi, if of sufficient size, located; but the many obscure affections involving the intestinal canal have not, so far as I am aware, received any elucidation by means of the rays of Roentgen.

I have made some experiments tending to ascertain whether c[illegible] uterus can be differentiated from [illegible]ng pregnancy. The results are most encouraging. After the fourth month a skiagraph of the pelvis leaves no question of doubt in the diagnosis and I am inclined to believe that gestation may be confirmed or eliminated as early as the eighth week.

The claim has been made and refuted, with about equal weight *pro* and *con*, that these rays exercise a germicidal power upon sundry micro-organisms. The question must be regarded as still open, but it is certainly very doubtful that they will be found to have germicidal properties of any magnitude. Cases of tuberculosis pulmonalis have been reported as much benefited by repeated exposures to the radiations from the vacuum tube, but whether the benefit is purely psychologic, is due to the counter irritation of the dermatitis generally resulting or is indeed the direct result of the action of the X-rays, *per se*, has yet to be demonstrated.

Not the least unfortunate of the unfounded claims made for these new rays was that they exhibited some remedial properties in cases of blindness. Edison and some of his enthusiastic followers imagined that the rays produced an effect upon vision, but no other physicist in the world, so far as I am aware, has been able to observe the phenomenon suggested by Mr. Edison; and this failure can not be assigned to inefficient apparatus, for there are many laboratories in which more intense and profuse X-rays have been and are produced than in Mr. Edison's laboratory. The error seems to have originated in a misinterpretation of the phenomena encountered.

A certain depilatory action seems to be exhibited occasionally, due partly to, in all probability, the same causes that produce the dermatitis Roentgenii. This property has been made use of in several instances for removing hairs for cosmetic purposes. Unfortunately the fact soon developed that the condition became eventually as bad if not worse than before the treatment was employed, owing to at least a return of the hairs removed and oftentimes an increased growth.

In May or J[illegible] '96, [illegible] first o[illegible]at a more or less severe inflammation of the superficial tissues would occasionally result from an exposure to the emanations from the vacuum tube, and as the number of cases of this inflammatory process rapidly increased and as they all exhibited substantially the same symptoms, *i. e.*, a dermatitis of peculiar nature, the name dermatitis Roentgenii was coined. Gilchrist, in the *Johns Hopkins Hospital Bulletin*, for February, 1897, reports twenty-three cases gathered from various periodicals. Many cases have occurred and have not been reported, so that the conclusion he draws as to the infrequency of the dermatitis is hardly warranted. I have myself seen nine cases, none of which have been reported, and I have authentic information relative to several others. In some points these cases differ widely, while in other respects they are very similar. The inflammation may be mild or extremely severe, depending on the location, the length of exposure, the condition of the tube and personal idiosyncrasy. The least time of exposure that has resulted in dermatitis, so far as I know, is fifteen minutes; numerous short exposures or a single long exposure are the conditions reported as observed in most of the cases. There is usually no sensation at the time of exposure, and for from twenty-four hours to twenty-one days thereafter the skin remains apparently perfectly normal. After this period of "incubation" the skin over the area exposed to action from the tube becomes bright red, reddish brown, dark brown or almost black; the epidermis is raised from the true skin by a serous fluid (either *en masse* or in bullæ), the scarfskin separates and comes off, leaving a bright red, raw-looking surface with a profuse, sero-purulent, ill-smelling discharge. There is at this time, usually, a sense of burning pain and soreness at the seat of the inflammation, which has been preceded in many cases by a brief period of partial anesthesia. The condition grows worse for from ten days to three weeks and then spontaneously heals, in the ordinary cases. In the more severe cases the true skin may slough off leaving an ulcerative surface that is very difficult to heal. The more serious results seem to have followed prolonged exposures or fairly long exposures repeated at frequent short intervals.

Several theories have been advanced to explain this phenomenon: 1. That it is caused by ozone. 2. That it is caused by ultra violet rays (*i. e.*, ultra violet rays of known wave length). 3. That it is due to electric action by induction. 4. That it is caused by particles of matter projected from the tube. The really rational explanation seems to have been overlooked.

1. If caused by ozone, the sides and palmar surface of the fingers and hand would be affected as well as the dorsum, when the dorsum is exposed to the rays and subsequently becomes affected. Also in the experiment of Elihu Thomson, the entire area of the hand within the field of radiation of the tube would have been affected, and not merely a limited area on one finger, corresponding to a window of clear German glass in a tube of thick blue glass; the finger having been exposed to the rays from the window and it alone having been subsequently affected. Certainly in this experiment, the conditions in regard to ozone were the same for all parts of the hand. There are also many other circumstances impossible to reconcile with the ozone theory.

2. That it is caused by ultra violet rays of known wave length: the experiment of E. Thomson previously referred to would exclude this theory, for the blue glass of the tube would offer no more obstruction to such ultra violet rays than would the window of clear German glass.

3. That it is due to electric action is hardly tenable, for the reason that the electric induction is small in comparison with the electrification often induced for therapeutic or experimental purposes and that in the latter case no such effect is produced.

4. The theory that it is caused by particles of metal projected through the walls of the tube has been advanced as a result of Tesla's suggestion that the rays are themselves streams of projected particles; the theory is, however, without any evidence to support it, and indeed the mass of evidence is directly opposed to such an assumption. Certainly no "material particles" have been found outside the tube. To be sure there is no direct proof that the inflammation may not be produced in the way suggested, but Gilchrist was unable to find any trace of metal in the cast-off skin in his case of dermatitis.

The conditions entering into the production of this inflammation are: 1. An exposure of not less than fifteen minutes within a comparatively few inches of an electrically excited vacuum tube emitting X-rays; 2, the condition of the vacuum and excitation of the tube; 3, idiosyncrasy. The first and third factors are well recognized and need no explanation; the second is the factor which seems to offer a key to the solution of the problem.

The vacuum is not a constant quantity. After the current has passed through the tube a certain time, the phenomena change, the tube exhibits increased resistance and other indications of an increase in vacuum; this increase in vacuum may be due to actual loss of contained gas, as claimed by Tesla, or to a condensation of the gas upon the inner walls of the tube. The latter, for various reasons, seems the more probable theory. As the vacuum increases, the character of the emitted rays changes. Commencing with a low vacuum, the rays emitted are of comparatively long wave length and limited penetrability; with increasing vacuum, the wave length decreases and naturally the penetrability increases. In all probability the rays from the higher tubes are, however, somewhat akin to white light, in that they are made up of rays of various wave lengths. The rays of longer wave length and little penetration, are more easily absorbed and produce more markedly the effects of transformed energy than do the waves of shorter wave length and greater penetration. This may be observed by comparing the appearance of a fluorescent screen when excited by the two extremes; in the one case the screen is brilliantly lighted up, but the flesh, as well as the bones of the hand, is opaque and a shadow of the hand alone is seen; in the other case the screen is less bright, but the flesh and even, sometimes, the bones of the hand may be quite transparent; similar phenomena may be observed if the photographic plate is substituted for the screen. Absorption of radiant energy must produce some effect; we see that such is the case with the fluorescent crystals and with the photographic emulsions; I am inclined to think that the dermatitis Roentgenii is nothing more nor less than the result of this absorption of radiant energy by the cells of the skin, and is parallel to the changes effected in the photographic emulsion.

We know that radiant energy falling upon the unstable molecules of a silver bromid emulsion, produces a rearrangement of the atoms resulting in a less complex molecule. We also know that organic cells are made up of rather unstable molecules. I can not but think that we have here to do with such a change. The radiant energy of the X-rays which are of comparatively long wave length, would be absorbed by the molecules of the first substance coinciding with their absorption band encountered, and if these molecules were unstable, they would suffer rearrangement of their atomic structure. Such a rearrangement, it is more than likely, would be, if carried far, sufficient to greatly modify the cell function and produce cell death. Apparently this is the exact condition produced, for the dermatitis shows every indication of being a superficial gangrene, and the sloughing process continues until the dead material has been cast out, when healing is spontaneous.

I have observed that dermatitis is more apt to ensue from exposure to low vacuum tubes than to tubes of higher vacuum, and that a very long exposure may be safely made, when the tube is of excessively high vacuum and the rays emitted are of great penetration. In the former case the vast majority of rays are unquestionably absorbed by the skin, whereas in the latter case but few rays are absorbed.

We should also expect, if this theory is true, to see more or less disturbance of the subcutaneous tissues following excessive exposures; and such is the case, for we find that prolonged exposure has resulted in sloughing of the true skin and underlying tissue; and that pain and soreness in and of the bones and joints has been observed repeatedly; and that cases of miscarriage in the latter months of pregnancy have followed long exposure to these rays The evidence seems to me conclusive.

The possible danger of dermatitis or other inflammatory process, should not deter us from employing this diagnostic aid. In the vast majority of cases no untoward consequence need be anticipated, if a few precautions are borne in mind The tube should be carefully examined and not used for diagnostic purposes when the vacuum is low; the minimum exposure necessary to secure a satisfactory skiagraph, when the tube is not too low, and the distance of the tube from the surface of the part exceeds six inches, will almost never produce a dermatitis. When the case is one requiring a prolonged exposure, or several repeated exposures, it becomes a matter of judgment, whether the urgency of the examination is sufficient to warrant the dermatitis which may ensue.

803 Sutter Street.

THE FALLACIES OF X-RAY PICTURES.

BY EDWARD A. TRACY, M D.

FELLOW OF THE MASSACHUSETTS MEDICAL SOCIETY, MEMBER OF THE AMERICAN MEDICAL SOCIETY
BOSTON.

Roentgen's marvelous work on the properties of the X-rays (their nature is as yet unknown) has already been productive of much good in surgery and medicine—almost entirely in the field of diagnosis. The application of his discovery necessitates the rewriting of the text-books on fractures and dislocations. Facts, heretofore "smothered in surmise" are clearly set forth by the radiographs. For example, no writer, of which I am aware, on fractures, suspected the frequency with which fracture of the ulnar styloid process accompanies Colles' fracture; yet this frequency has been demonstrated by radiographs of Colles' fractures.

While much has been gained in accuracy of diagnosis by the aid of X-ray pictures, there is one branch of practical medicine where harm is threatened by their employment. I refer to medical jurisprudence. X-ray pictures have been already admitted as evidence in some courts. Their indiscriminate admission will hurt the cause of justice—because they can easily lead to fallacy or error. Their use as evidence of injury, is only safe when certain conditions have been fulfilled, in their taking and presentation. I shall briefly indicate further on what these conditions are.

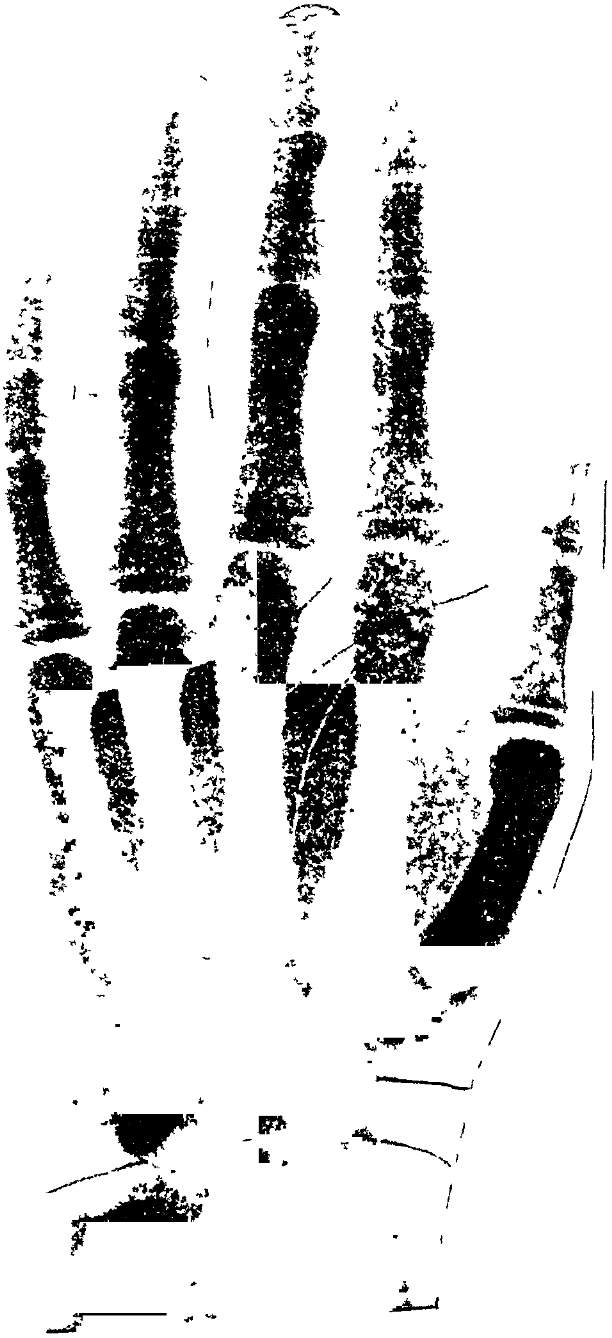

Figure 1

In all X-ray pictures there is distortion. The reason is X-rays emanate from a point, and are not parallel. Interference with these rays follow the ordinary physical and mathematical laws of rays emanating from a point. (Of course it is understood that there is neither reflection nor refraction of the X-ray.) Thus the nearer to their source is an obstruction to the rays, the larger will be the resultant shadow or picture; the size of the shadow depends also upon the nearness of the object to the surface upon which the shadow falls; the further the surface from the object, the larger the shadow. If we had for a source of X-rays a surface as large as the object to be pictured, there would be no distortion, for the X-rays would be parallel. X-ray pictures in that case would be easy of comprehension, and never misleading. To read correctly the lesson of an X-ray picture, the obliqueness of X-rays must be kept in mind, and mental correction made for the disproportion and distortion caused by this obliqueness.

To illustrate the foregoing remarks, I present Figs. 1 and 2. They are plates of radiographs of the same hand, the right, of a boy 13 years of age. Before taking them, I thought that the relations of the palm and wrist lines to the underlying bones could be accurately determined by radiography. My plan was this: I covered the palm and wrist lines with pieces of copper wire. The wire was attached to the skin by means of collodion and cotton fiber. The copper wire being resistant to penetration by the X-rays would cause dark lines upon the picture, and thus I hoped to have the palm and wrist lines represented with the bones, and their relations shown. The palm and wrist lines are represented but their relations are not accurately pictured. This is proven by the plates. Fig. 1 is from a radiograph of a hand with its palm toward the sensitized plate. Fig. 2 is of the same hand turned over so that its back was toward the plate. The relation of the palm and wrist lines to the bones had not actually changed by simply turning over the hand; the pictures represent these relations to have changed, and therefore are fallacious. If our source of X-rays was so large that the rays streaming through the object were parallel, such divergence would not exist, and the lines representing those of the palm and the wrist would coincide in both pictures.

Figure 2.

Besides the want of coincidence in the palm and wrist lines in both pictures, I invite attention to the difference in size of the thumb metacarpal in the pictures. In Fig. 2 the thumb metacarpal is pictured as thicker than in Fig. 1. The pictures represent a difference in size where none exists, as both are pictures of the same bone. Hence, again, X-ray pictures are fallacious. This difference in size is explained thus: In Fig. 1 the hand was palm against the sensitized surface of the plate, and therefore the thumb metacarpal bone was nearer to the plate, than when the hand was with its back against the plate as in Fig. 2. The thumb being nearer the plate in the first position than in the second, its shadow was smaller, so pictured in Fig. 1.

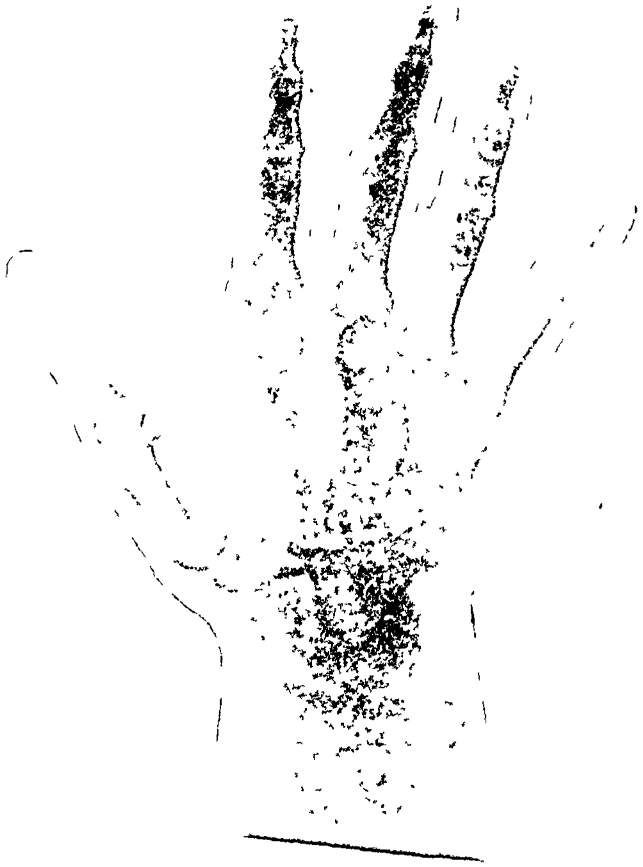

Figure 3.

Besides the variations in the picture caused by the distance of the object from the source of the X-rays, and the variations caused by the distance of the object radiographed from the sensitized plate, there are variations caused by the position of the object with relation to the direction in which the X-rays strike the object. This is shown by Figs. 3 and 4. In Fig. 3 we have the bones shown thicker than in Fig. 4 and with curious spur-like exostotic deposits upon the metacarpal bones. *Both are radiographs of the same* *hand.* The difference in the pictures was caused by the difference in position of the Crooke's tube when they were taken. In taking picture 3 the tube was more to the ulnar side of the hand than when taking picture 4.

In my possession is a plate in which the deformity caused by Colles' fracture is quite closely simulated by a similar change in the position of Crooke's tube. The plate is of a normal wrist. The importance of this from a medico-legal point of view need not be enlarged upon.

I have thus shown X-ray pictures to be fallacious and misleading—and described some of the causes of these fallacies.

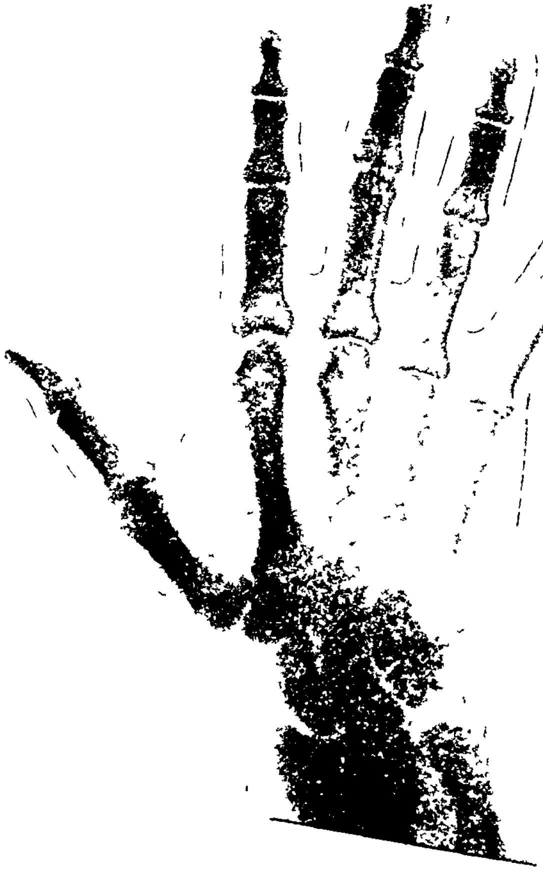

Figure 4.

Because X-ray pictures can be fallacious, should they be excluded from court as evidence? Certainly not. It is well to know their limitations, and to remember that appearances may deceive. X-rays, properly used, are as a search-light in the exposition of bone lesions. But the lesions must be pictured from different directions, and the resultant pictures compared with pictures of the normal opposite member. Moreover the pictures of the injured member and those of the opposite normal member, must be taken with the same relative positions of the Crook's tube, the limb and the sensitized plate. Then can truth be arrived at, and truth is essential for justice.

99 Broadway.

Salicylate of Methyl in Scarlet Fever Arthralgia.—Professor Roger has secured rapid and marked improvement in the arthralgia accompanying infective diseases and especially scarlet fever, by the use of salicylate of methyl. Twenty to forty drops are applied to the articulation morning and night, which is afterward wrapped in oiled silk.—*Semaine Méd.*, August 18.

CORNEAL BURNS FROM ACCIDENTS IN THE USE OF CURLING IRONS. REPORT OF SIX CASES.

JOHN O. McREYNOLDS, B.Sc., M.D.

DALLAS, TEXAS.

This unusual form of traumatism is worthy of mention, because of the severity of the pain, the grave apprehensions of the patient and the uniformly speedy and complete recovery. In the six cases that have recently come under my observation (Mrs. W., Miss L., Miss E , Miss M., Miss L. and Miss H.) the injury was received directly upon the cornea by dropping the hot curling-iron upon the open upturned eye. The extent of the injury has varied from three square millimeters in area to a third of the corneal surface.

In the severer cases the pain has been very intense unless continually relieved by local anesthetics. The seared superficial epithelium in a few hours exfoliates in a white opaque mass, leaving beneath a denuded corneal surface, which soon becomes, under favorable treatment, re-covered with normal epithelium and within a few days the eye is perfectly well. In corneal injuries in general I should object to the employment of cocain, because of its bad influence upon nutrition, but in this form of injury, in which the pain is so excruciating and the danger of subsequent ulceration so slight, I have considered it prudent to use a weak solution or ointment of cocain or eucain to secure rest for the patient. For this particular purpose the eucain has the advantage over cocain in that it increases rather than diminishes corneal nutrition and also is capable of being thoroughly sterilized by heat. The additional indications are the frequent use of mild antiseptic solutions, the moderate employment of a mydriatic and the application of a light bandage to obtain rest and protection for the wounded eye.

GENERAL IMPRESSIONS FROM SIX YEARS USE OF THE OLD TUBERCULIN.

Read before the British Medical Association at Montreal, Sept. 2, 1897.

BY JAMES T. WHITTAKER, M.D.

Robert Koch announced the discovery of tuberculin at the Tenth International Congress at Berlin, August, 1890.

The publicity of the occasion, the fame of the author, above all the defiance of the disease to all treatment hitherto, lent peculiar interest to the discovery. The suddenness of the announcement was another factor. No one had even an inkling of the work leading up to it.

The declaration of the discovery of the tubercle bacillus in 1882, though credited by many of the members of the critical audience in the Berlin Physiological Society to which it was presented, met with so much scepticism in the profession at large as to have been practically disbelieved. Most of the leading medical journals discredited it; many of them derided it. When the truth asserted itself the disbelievers found themselves punished for incredulity. So, although the problem was harder. belief was easier on this occasion. In fact, there was reaction to the other extreme and more was expected of the remedy than was expressed in the modest claims of the author. This was the reason why medical men, who represent the [illegible] au[illegible] and [illegible] branch of human [illegible] re[illegible] and began to experiment with it in a way and in cases in which the author, to use the mildest terms, had never advised it.

The disappointment which followed was intense and the expression of it was not without bitterness. In fact, we have just now reached a period when any renewed advocacy will be listened to at all.

One of my former students brought me directly from Berlin a small quantity of tuberculin, Jan. 15, 1891, as the very first importation into this country, and with this specimen I began the use of the remedy in the cases at the Good Samaritan Hospital at that time. These were four cases of tuberculosis pulmonum and one case of scrofula, to which I will allude again.

My first use of the remedy was entirely therapeutic and I did not begin to avail myself of the immediate action of it in diagnosis for two or three years. When it was used in this way the results were found. it is needless to say it, much more striking and satisfactory. The use of tuberculin should be studied, therefore, from the double standpoints of diagnosis and treatment.

The value of it in the disclosure of tuberculosis in man was not at once rightly recognized, on account of alleged dangers in the use of it; but in cattle it soon met its proper appreciation, and is perhaps nowhere more extensively and satisfactorily used than in the United States.

Aside from the objections urged by ignorant and prejudiced people, not worthy of notice, four apparently valid arguments accumulated in the course of time against the use of tuberculin in man.

1. That the reaction occurred in the absence of tuberculosis. This objection has been met by the demonstration of concealed depots.
2. That the reaction occurs in other diseases, syphilis, lepra, actinomycosis, etc. This objection has been met by the demonstration of tuberculosis coincident with or complicating these maladies.
3. That the reaction will occur in the most quiescent case even where the bacilli are not only concealed but encapsulated and depots are partly calcified. This is no objection at all, but a most striking confirmation.
4. That the use of it is dangerous; that it not only awakens the disease from latent sources but disseminates it over the body and thus leads to auto-infection and increases the danger of infection of others. This conclusion rests on a false premise and confounds the *post* with the *propter hoc.*

I will not take the time to further discuss theoretic objections but content myself with the repetition of a statement, made on another occasion, that I had used tuberculin every day in hospital and private practice for six years in now nearly one thousand cases and have never seen any kind of evil result beyond the characteristic reaction. Koch himself declares the fear of danger to be a "foolish prejudice." He says he has never seen "even the slightest intimation of any mobilization or transfusion of tubercle bacilli" in the use of tuberculin as a diagnostic agent in over one thousand cases, and this experience he thinks "should put the diagnostic value of it in man on the same plane as in animals." My own use of tuberculin has been nearly exclusively for therapeutic and only exceptionally for diagnostic purposes.

In a paper read before the Association of American Physicians in May and published in the "Transactions," I reported a number of cases, doubtful and obscure, in which the diagnosis, positive and negative, so far as tuberculosis was concerned, had been easily established and mostly after failure with other means, by a test dose of tuberculin; thus in cases of neurasthenia, nightsweats, joint disease, laryngitis, pulmonary tuberculosis, peritonitis, fistula, etc. Since this report I have had a striking illustration of the penalty which attaches to over-confidence in diagnosis and neglect of using the most approved method of study. This will be the only case which I will report. June 10 I was called in consultation by Dr. D., a good surgeon in Cincinnati, to aid in the diagnosis of a case of enlarged glands in the neck in a patient, a woman, aged 67. The glands had begun to grow three months before and now formed a good sized mass under the angle of the right jaw, extending down behind and below the sternomastoid muscle. There was some pain, and within the past few weeks there had been slight fever. The glands were deep-seated and hard. The patient had enjoyed good health hitherto and had no other discoverable disease. The rapidity of the growth, the presence of pain, the exemption of any affection of the lungs, above all the age of the patient, led us to declare a diagnosis of carcinoma, probably sarcoma of the cervical glands, and to advise immediate extirpation. The operation was tedious and bloody (as had been expected) and the patient succumbed in three weeks. I learned these things by letter from the surgeon, together with the fact that the glands upon microscopic and bacteriologic examination turned out to be tuberculous. Now, although extirpation is often the best treatment of an adenopathy of this kind, I should myself with a true knowledge of the disease have advised against an operation in this case at that time.

The mode of action of tuberculin, to which I allude merely from a clinical standpoint, has met with various explanations. Certain it is that together with leucocytosis and fever a sharp hyperemia is developed extending over the entire domain affected, and in this process toxins are formed or liberated which produce the characteristic reaction and give partial immunity to the poisonous products of the tubercle bacillus. The immediate benefit which nearly all patients feel is due to this immunity. The proper principle of treatment consists in pushing the development of this toxin as rapidly as possible this side of extreme reactions, before tolerance to the tuberculin itself is established in the body. Most of the protection of the body against the action of poisons is based, as we know, upon tolerance, which is probably secured by increasing the antitoxic action of serum of the blood. The patient affected with tuberculosis is not fatally poisoned by the products of the tubercle bacillus because of tolerance to the products of it begotten in this slow development. When these products are developed too rapidly the body is overwhelmed and succumbs. But the tolerance to tuberculosis as a rule is so great that individuals live for years and decades of years, and often recover entirely. The body becomes adjusted to the effects of the poison and sometimes shows in this process remarkable changes. Thus the disposition may be actually improved by it. It was Klebs, who makes anyhow such close and curious observations, who first spoke of the singular sweetness of disposition and loveliness of character sometimes seen, especially in women, the sufferers with slow phthisis. Men, it seems to me, are rather made more irritable. The true principle of treatment with tuberculin is to secure the action of it before tolerance to it is established, for so soon as it is tolerated it loses its effect. Unfortunately there is as a rule, not time to secure immunity to the products of the tubercle bacillus before this tolerance to tuberculin is established, and so the benefit experienced at first is lost in the later treatment. For with tolerance the toxin ceases to increase the antitoxic action of the blood, and any continued use of it after this time seems really to lessen it. So when the tuberculin fails to do good and the disease reasserts itself, the use of the remedy should be stopped. Time should then be allowed to lapse, several weeks being required in most cases, and then when the tolerance is lost the treatment should be begun again. Thus the successful treatment of tuberculosis takes time, a long time, months and years, about as long as does the successful treatment of syphilis, which is usually a matter of years. The physician who expects to cure a case of tuberculosis in a few weeks will soon become discouraged and will probably join the ranks of medical men who denounce and decry the means.

The first dose for the case of lightest infection (suspected) should be 5 mg., the second 10 mg. or one centigram, the third two centigrams. These doses may be given on succeeding days, or better, every other day, preferably in the evening that the temperature records may be properly observed on the following day. Failure to get reaction from three tests excludes concealed tuberculosis. The crude tuberculin diluted one hundred times preferably with a 0.5 per cent. solution of carbolic acid, makes a 1 per cent. solution of which one interspace of the Koch syringe represents one centigram. One interspace of this 1 per cent. solution diluted ten times makes a milligram. For therapeutic use I begin with one-tenth of a milligram.

In my first use of tuburculin I was able to adhere rigidly to the rules laid down by Koch, but I was not able to select the cases or to limit myself to the first stages of the disease, the phthisis incipiens. In fact, every one of the cases of lung disease was advanced to what is commonly called the second stage, phthisis confirmata, and one of them was so far advanced as to constitute a phthisis consumata. The remedy was used in this case in infinitesimal dose, simply *ut solaminis causa.* The case of scrofula ultimately, *i. e.* in the course of two years, made a good recovery, while the cases of phthisis pulmonum all died in from four to six months. It was impossible not to feel disappointed and somewhat discouraged at the result. But on comparing subsequently the course of similar cases treated with tuberculin with other cases, it was seen that the process of the disease was slower in the first cases; for, some improvement pretty much always sets in at first. We had however nearly uniform results to report in hospital practice, an improvement for a time with subsequent continued progress downward interrupted with many stages of quiescence and occasional temporary gain. In explanation of the temporary improvement it became plain to see, as cases multiplied, that after making all allowance for the all-powerful influence of suggestion, and some for the better hygiene of hospital life, there was still room for much to be granted to the specific treatment.

It was a long time before the reason of the continued progress of the disease was ascertained, but it became apparent at last, with continued examination of the sputum, that direct product and derivative of the disease, the closer examination of which had led to the discovery of the tubercle bacillus to constitute the luminous epoch in the history of the disease. But all attention had been directed to the detection of this bacillus in the sputum hitherto, to the neglect of other micro-organisms. As examinations multiplied in competent hands it was soon seen, or perhaps I should say, the facts already known became better appreciated, that the new advances or relapses marked by chills and sweats were due to invasions of other, especially of the pus-producing, micro-organisms, and that the disease had passed beyond the domain of tuberculosis into the wider realms of sepsis. It was at this time that the school of Koch proposed to call the seesaw temperature of hectic the streptococcus curve. The reason of the failure of tuberculin in the further course of the disease now became apparent. It was not to be expected that tuberculin, a product of the tubercle bacillus, would inhibit the growth of or destroy the influenza bacillus, the diplococcus or the pyogenic micro-organisms. The truth is, the great majority of cases in hospital practice are advanced beyond the stage of pure tuberculosis. They are cases of mixed infection or sometimes of secondary infection and belong not so much to tuberculosis as to septicemia.

The results of the use of tuberculin in private practice are more encouraging. In ordinary house practice cases are encountered in every stage, and the majority, because of the long duration of the disease, are advanced to the second stage, but the hygienic environment is better as a rule, that is, there is more breathing room, more outdoor life, including here the advantage of change of climate, more comfort in every way; as a rule to which there are many exceptions there is less auto-infection and less homesickness, and all that without saying goes with gregarious man. I had the influence of this factor impressed upon me once by the remark of a big, strong-looking man, who came back from Colorado too soon, with the apology: "Doctor, I am going to stay home; I had as leave be buried under the ground as on top of it."

But the advanced cases in private practice in the long run took the same course. The disease, after a temporary check, would reassert itself with chills, often of origin sudden and inexplicable, with hectic, night sweats and final dissolution. But every now and then there were agreeable surprises. The progress of the disease would be checked for a longer time, or the whole condition would be raised to a higher level, that of several months or several years before. In these cases the bacilli would diminish and sometimes disappear altogether and the gain in spirits, which is quick in phthisis, the *spes phthisica*, would exceed the gain in weight.

Just in which cases this gain would occur or in which it would fail to show itself could not be foretold. As in so many other things, it was necessary to try to find out. Sometimes it would be impossible to know whether the improvement was really due to the tuberculin or to conjoined treatment, but as time advanced and cases multiplied the feeling would grow that the cases treated with tuberculin off and on, more especially for a long time and judiciously, that is, with the same caution as in the use of any other agent in the materia medica, that these cases did the best. It was always easy enough to study control cases in patients who were themselves, or had been by their physicians, prejudiced against the use of it.

So that when the diagnosis was clear, as established in a plain case by the physical signs, in a doubtful case by the discovery of the tubercle bacillus, or in a still more doubtful case by a test injection of tuberculin, I made it a practice to use it tentatively in every case, with the consent of the patient, never without it, and then continue with it or abandon it according to the results.

Some of the differences in results could be pretty definitely attributed to the kind or degree of the mixed infection, some to the localizations elsewhere in the body and some to the site of the original deposit. For instance, influenza cases, *i.e.*, cases complicated by influenza, do badly as a rule. Caries of the vertebræ, of the tarsus or carpus make ugly complications, while deposits in the pulmonary veins or thoracic duct or irruption into these vessels inundate the body to produce phthisis florida and miliary tuberculosis. We recognize these cases often after a very short examination and appreciate at once their ominous character. The continued feeding of the body from these depots makes futile every kind of therapy until more exact localization may be effected, perhaps by some kind of penetrating light, and destruction or extirpation become possible by galvano-therapy or by the knife. At the present time they constitute the despair of medicine, and the use of tuberculin is actually contraindicated in them. I know of no other contraindications.

The best results are obtained in office practice; in the first place in the way of diagnosis. It is a great satisfaction to be able to clear up a concealed case and to declare an exact diagnosis of a disease treated hitherto without a diagnosis or for something else. Thus an obstinate or frequently recurring dyspepsia, an amenorrhea, a neurasthenia, an anemia, a rheumatism, an adenitis, a little low fever (to say nothing of acute cases of chills, night sweats, catarrhs and coughs), may have their true nature revealed in this way. These are the cases (aside from the chills and fever) in which treatment furnishes the best results. Tuberculin gives good results also in childhood. Children react favorably to tuberculin, much more so than adults, so that the so-called apex catarrh of childhood will often clear up and disappear in them within three weeks.

Aside from these cases the treatment must be persistent and good judgment must be used in dosage; rather too little than too much. I have never seen any bad results from the use of tuberculin, because I always endeavored to secure a slow tolerance, so that individuals who react at first to a few milligrams become later insensitive to one hundred times as much; in fact, at last to one thousand milligrams. The evils ascribed to it I believe to be due to the disease itself, for I have seen them oftener before the use of it. But it is easy to conceive that the patient would suffer under excessive reactions and that repeated excesses might do permanent harm. But, *ex abusu non arguitur ad usum.* It is a maxim of the law, good also in medicine, that we may not from abuse argue against use.

The highest value of tuberculin is the diagnostic value, which is supreme, and which enables us to distinguish the disease at the start as a tuberculosis before the development of sepsis or other complications which go to make up that composite picture we call phthisis.

THE PHYSIOLOGY AND THERAPEUTICS OF THE THYROID GLAND AND ITS CONGENERS.

BY H. GIDEON WELLS, PH.B.
CHICAGO, ILL.

(Awarded the L. C. P. Freer medal, Rush Medical College, 1897.)
From the chemic and pathologic laboratories of Rush Medical College.

(*Continued from page 901.*)

After having tested all the materials used, as to their purity, familiarity with the method was obtained by adding to pure gelatin, known quantities of iodid of potassium and going through the process repeatedly. At first an open crucible was used and it was found to be impossible to regain more than one-half of the iodin. It is probable that in this case iodic acid compounds were formed in spite of the excess of the alkali, since this loss disappeared on the substitution of a covered silver crucible. (A platinum crucible can not be used since this metal is attacked by caustic alkalies.) Another source of loss occurs on the addition of the acid to the filtrate. This must be done in a flask with a small mouth and the acid added very gradually, otherwise there is loss through effervescence. By observing these points it was possible to obtain at least nine-tenths of the original amount, which was the same limit of accuracy that Baumann claimed to reach. During the fusing it is necessary to prevent the contents of the crucible coming in contact with the lid, since in these cases no matter how carefully the deposited material was removed, the loss was always greater than could be readily explained even by considering all that touched the lid as lost.

The first series of actual analyses was made on people who, according to the history sheets, had lived at least some years in this city, who had not received iodin for at least some time before death, and whose glands appeared to be in every way normal. Twenty such glands were analyzed, the results and the main features of each case being shown in the following table:

	Sex.	Age.	Cause of Death.	Weight of gland. Grams.	Iodin p'r gram. Mgrs.	Total mgr. Iodin.
1	M	45	Chronic nephritis	2 60	2 86	7 47
2	M	60	Brain tumor	4 39	2 61	11 75
3	M	60	Tubercular peritonitis	2 59	1 67	4 33
4	M	35	Pneumonia	3 88	2 58	10 00
5	M	35	Peritonitis	3 84	2 66	10 21
6	M	45	Pneumonia	10 59	0 99	10 47
7	M	44	Pneumonia	6.33	1 52	9 62
8	M	28	Endocarditis	3 71	2 74	10 17
9	M	26	Liver abscess	4 47	2 58	11 53
10	M	46	Chronic nephritis	5 16	1 82	9 41
11	M	50	Appendicitis	5 79	1 98	11 46
12	M	25	Pulmonary tuberculosis	4 88	2 28	11 15
13	M	49	Carcinoma of stomach	3 77	1 98	7 46
14	M	30	Multiple endotheliomata	9 68	1 82	17 62
15	M	35	Acute nephritis	6 66	1 52	10 12
16	M	41	Chronic nephritis	6 53	1 98	12 93
17	F	25	Syphilitic myelitis	5 14	1 82	9 36
18	M	26	Pneumonia	9 01	1 93	17 39
19	M	60	Meningitis	5 24	1 52	7 96
20	M	65	Pneumonia	4 10	1 22	5 00
			Average	5 37	2 10	10 79

We find here a most surprising difference from the results obtained by Baumann, especially in his Freiburg series. While each gland averages in weight less than two-thirds the weight of the Freiburg glands yet each gram contains just six times as much iodin, and the total amount in each gland is over four times as much. Even in comparison with the Berlin series the difference is still greatly in favor of the Chicago glands, which contain over twice as much iodin in each gram, and over one-half more in the entire gland.

In interpreting these results we must consider that, in natives of Chicago, goiter is an even less common affection than it is in Berlin. Accepting this fact, the figures bear out the belief that the amount of iodin is inversely proportional to the amount of goiter in any given district. The effect of chronic diseases in reducing the amount of iodin contained in the gland, which Baumann mentioned, is not corroborated by this table, for the cases of chronic diseases, Nos. 1, 8, 9, 10, 12, 13 and 16 show an amount of iodin fully up to the average. It will be noticed that the glands of people 60 years of age and over, Nos. 2, 3, 19 and 20, with one exception, are much below the average, and it would perhaps have been better not to have used glands from people past middle life. The lowest proportion of iodin obtained in any one gland was 0.99 mg. to each gram (case 6) but it was in the largest gland in the series, so that the total amount in the gland was almost exactly the average. In general it can be stated that the weight of the gland is inversely proportional to the amount of iodin in each gram, and this rule applies to most forms of goiter. Thus it would seem as though it were necessary to keep the total amount of iodin in the gland at a certain standard, and that lessening the proportion of the iodin in the gland caused an increase in the size of the organ to make up in quantity for the lack of quality.

Two glands were omitted from this series because of their exceptionally high iodin content, which made it impossible to consider them as normal. Neither of these people had taken iodin, at least during their last illness. They were:

1. Man, 45 years of age, dying from hypertrophy and dilatation of the heart. Gland contained 34.1 mg. of iodin, weighed 6.7 grams, and in each gram was 5.09 mg. of iodin, the largest proportion obtained in any gland.
2. Man, 33 years of age, dying from a tumor of the brain. The gland contained 30.28 mg. of iodin, weighed 8.65 grams, and contained in each gram 3.5 mg. of iodin.

The following table shows the result of the analyses of the glands from babies and children:

	Sex.	Age.	Cause of Death.	Weight of gland. Grams.	Iodin p'r gram. Mgrs.	Total iodin. Mgrs.
1	F	term	. . . .	0.135	traces.	traces.
2	M	term.	. . . .	0.465	traces.	traces.
3	F	term.	. . . .	0.73	traces.	traces.
4	M	4	. . . .	0.68	0.11	0.076
5	M	1	. . . . . .	0.18	0.12	0.076
6	M	1	. . . . .	0.58	0.92	0.532
7	F	7 yrs.	Phthisis.	1.61	1.98	3.19

This series is short because of lack of material, but it is still very significant. In the first place, even in stillborn children, traces of iodin, representing amounts not over 0.03 mg. were obtained in every case, while Baumann failed to find it in the great majority of Freiburg children who had lived even several months. The constant increase from traces in new-born children to estimable quantities in the children that had lived a month, and to relatively considerable amounts in children of four and seven years is also very interesting. The rather marked increase in the iodin, after but a few weeks existence, suggests the probability that the thyroid of the mother performs the functions both for herself and the child. In support of this idea are the facts that the thyroid increases in size during pregnancy, and also that up to the time of birth the gland of the child contains but little colloid; and also, Halsted has observed, in pregnant, partially-thyroidectomized bitches, the symptoms of athyreosis, when not present before, appear soon before parturition and disappear soon after.

A series of twelve normal glands from Boston and New York was also analyzed. As in the other series the analyses were all made in duplicate, and the results were not accepted unless they agreed closely. In this series one gland was not included. This was from a man 55 years of age, cause of death not known, weight of gland 5.99 grams, amount of iodin in each gram being 4.79 mg., total amount of iodin in the gland 28.69 mg. The other results were as follows:

	Sex.	Age.	Cause of Death.	Weight of gland. Grams.	Iodin p'r gram. Mgrs.	Total iodin. Mgrs.
1	M	30	Phosphorous poisoning . .	5.18	2.36	12·03
2	M	45	Suffocation.	3.65	4.94	18.03
3	F	40	Pneumonia.	4.43	1.90	8.42
4	F	25	Appendicitis	3.84	2.58	9.13
5	M	55	Pneumonia	4.77	1.90	9.06
6	F	40	Pneumonia	3.54	4.56	16.11
7	F	60	Chronic nephritis	3.81	2.13	8.12
8	M	60	Pneumonia	3.47	1.14	3.86
9	F	35	Mitral stenosis	6.37	2.20	14.01
10	M	17	Poisoning.	3.44	2.51	8.63
11	M	25	Pneumonia	4.65	2.71	12.74
12	M	55	Meningitis.	6.18	2.66	16.11
			Average	4.17	2.61	11.80

It will be observed that while the individual glands show much greater variations in their iodin content than do those in the Chicago series, yet the average amount for each gland is but a little higher. The average weight of each gland is about one gram less, but the amount of iodin in each gram is somewhat higher. In two of these cases the proportion of iodin is very large, approaching 5 mg. to each gram, while the largest amount in the Chicago series was but 2.86 mg.

On account of the great variations in the total and proportional amounts of iodin in the glands of this series, the writer does not believe that he is justified in drawing any conclusions from this table, beyond that, that in all probability the iodin content in Chicago is about as large as in glands from the seacoast. Fortunately there are on hand several more glands from the same source, and these will be analyzed and the results added to the same table. In the time available for this work it has not been possible to finish this series, nor even to touch the glands from other localities, for even with the colorimetric method quantitative determinations of iodin can not be made with great rapidity and be of value. However, the work on this subject will not be stopped with the completion of this paper, but the material on hand at least will be utilized, and if the results are of sufficient interest a paper on this feature of the work alone will be prepared.

Physiology.—Up to the time that Schiff and Horsley proved that the thyroid gland was an organ necessary to the well-being if not to the life of its possessor, many theories, mostly founded upon mere supposition and without any experimental basis whatever, had been advanced by physiologists to explain its purpose and part in the animal economy. These theories were generally discarded, however, after a brief investigation, as not completely meeting the indications. Since the time that the epoch-making discoveries referred to, pointed out the direction in which all further efforts should be directed to obtain results of value, a vast amount of experimental evidence has been produced from innumerable sources, which has thrown an entirely new light on the subject, yet has merely supplanted old theories with new. However, this difference does exist; the theories now under consideration are based upon facts obtained as the result of the work of careful investigators along the lines of experimental physiology.

Before considering these theories, it will be well to set down the chief facts that we now possess, and which must form the basis upon which we found our consideration of these ideas. Practically all our knowledge of the action of the thyroid gland is based upon the changes observed in man and animals when they are under one of two conditions, which are:

1. When the animal is receiving less than the usual amount of secretion from the thyroid, as in extirpation experiments.

2. When the amount of secretion in the body is above normal, as when the thyroid extract is being administered.

These two headings include not only the results obtained by experiments, but also those obtained from clinical observations, since here the symptoms are due to a hypo-activity, *e. g.*, myxedema and cretinism; or possibly sometimes to hyper-activity, *e. g.*, exopthalmic goiter.

In the first case, when the subject is not receiving the full influence of the thyroid gland, we observe a series of symptoms that can be classified as *a*, nutritional; and *b*, nervous.

a. The nutritional changes seem to be of such a nature that the metabolic changes throughout the tissues do not proceed to their full extent, and the power of reproduction of the cells is altered. As a result of the first the connective tissues stop in their metabolic processes just short of completion, leaving them, as Semon has suggested, in an embryonic condition, that is, in the form of myxomatous tissue which is their embryonal representative. From this cause occurs the peculiar condition of the skin observed in people suffering from loss of functional activity or from removal of the thyroid, which gives to this condition its name, myxedema. This change is not confined to the subcutaneous connective tissue, but is a general change, for Halliburton has shown that in the blood of monkeys which were in a myxedematous condition as a result of thyroidectomy there is demonstrable a considerable quantity of mucin. Because of the failure of complete reproduction, or through some alteration in the process, we observe a change in development in young animals, quite analogous to the condition in children that have not possessed an active thyroid, known under the name of cretinism. Besides this there seems to be some alteration in the gas exchange of the blood, since in thyroidectomized animals the amount of carbon dioxid is increased and the oxygen diminished until the arterial blood may be below the normal venous standard.

b. The nervous system is apparently greatly affected, the most marked symptoms from this source being those due to the excitation of the muscular fibers, viz., twitching, tremors and spasms. These undoubtedly proceed from the lowest centers, since Horsley has observed them in monkeys subjected to ablation of the motor cortex, and Munk found that they were not affected by division of the cord, while Schiff has proven that they are not of peripheral origin since they are completely arrested by section of the motor nerves. Later these symptoms are followed by a lessening of the power of a voluntary action, as well as loss of sensation, which result in the lethargic condition so well illustrated by the cretin. The thermotaxic apparatus is also affected, so that the body temperature falls to three or four degrees below normal. Lorrain Smith has observed that the reaction of thyroidectomized animals to changes of temperature is abnormally rapid, so that in such an animal exposed to cold an increased production of carbon dioxid begins immediately, instead of being delayed for some time as in normal animals. Moreover it is noticed that many of the symptoms of athyreosis are alleviated by artificial heat. These nervous symptoms may be due to alterations in nutrition, either directly affecting the nerve cells, or producing secondary changes in them through degeneration of the nerve centers.

In the second case, when the thyroid preparations are administered to animals experimentally, or to man therapeutically, effects are produced which are quite different from those described above, as would be expected, yet they can be separated into the same two classes.

a. Nutritional: The process of metabolism throughout the body undergoes a marked change, which is shown best by the urine. This is considerably increased in quantity, it contains a greater amount of urea, as well as chlorids and phosphates, as has been shown experimentally by Roos, and clinically by Napier and others. At the same time the weight of the subject diminishes, more particularly if it be above normal because of fat deposition. This decrease in weight is constant and considerable, and Wendelstadt has been able to demonstrate that but one-sixth of the loss can be attributed to the nitrogenous compounds as shown by the increased nitrogen content of the urine, the rest being due to loss of water and of the fat itself through increased oxidation.

b. Nervous: Of these the most prominent clinically is the palpitation of the heart, which is a certain indication that the dosage has been carried too far. With it come headache, nausea and vomiting, and if the remedy be pushed still farther the pulse and heart weaken to a dangerous degree. Sometimes glycosuria is produced, which can be attributed to some action on the diabetic center since it may develop into a true diabetes mellitus. Schäfer has also shown that if thyroid extract be injected into the veins of healthy dogs there follows an immediate fall of blood pressure without any considerable change in the rate or force of the heart beat, due to dilatation of the vessels throughout the body.

With these facts as a basis the theories that may be found in text-books and articles on the subject may be critically considered. They may be enumerated as follows: 1. An adventitious organ without function. 2. To give form to the neck. 3. Having mechanically some influence on the voice. 4. Acting as a cushion to prevent injury to the structures of the neck. 5. Regulator of the blood supply of the brain. 6. Having a controlling influence over sleep. 7. Having some connection with the sexual apparatus. 8. Having control over respiration. 9. A blood-building or blood-destroying organ. 10. Influencing the quantity of mucin in the body. 11. Having some connection with senile changes. 12. Producing some substance neutralizing the toxic materials in the system. 13. Producing some substance necessary for the metabolism of the body.

The first four of these theories will be found only in some of the older text-books, and of course are only attempts to account for the presence of this mass of tissue in the neck without any obvious function.

The fifth and sixth are practically the same, it having been supposed that the gland by its swelling produced pressure on the carotids (Maignien), or that the vessels in the gland became greatly dilated on certain occasions, and so the blood instead of going to the brain became side-tracked, as it were, and so regulated the cerebral supply. This theory also received a supposed confirmation in the fact that in exophthalmic goiter, in which the vascularity of the gland is greatly increased, there are many cerebral symptoms. These theories, however, are entirely negatived by the results of removal of the gland.

The seventh theory is founded on the following observations: The thyroid gland becomes greatly enlarged during menstruation; it also enlarges during sexual excitement; goiter most often develops at puberty and at the menopause; goiters increase in size at delivery and decrease a few days after; exophthalmic goiter improves after delivery; the thyroid gland atrophies at the climacteric. Still the writer has failed to find any references to loss of sexual appetite or change in the sexual conditions in diseases of the thyroid or after its removal. Also a case of pregnancy in a cretin has recently been reported by Townsend. It may be here remarked that diseases of the thyroid gland show a special predilection for the female sex. Fischer has collected statistics showing that from 80 to 90 per cent. of all cases of goiter and 86 per cent. of the cases of myxedema, occur in women, while exophthalmic goiter seems to attack the same sex chiefly. Halsted has three times observed pregnancy in bitches that had lost portions of their thyroid glands, impregnated by dogs in the same condition. These bitches showed none of the symptoms of athyreosis (not having lost a sufficiently large part of their glands) until just before giving birth to their litters. Then the symptoms became very marked, but disappeared soon after parturition. What is especially remarkable is that in every case the pups had thyroid glands many times the normal size observed in pups of the same weight.

The eighth hypothesis is also an old one based upon the increase in size of the gland noticed during forced expiration, as in asphyxia, and also in animals when breathing rapidly, as dogs returning from the chase. The dyspnea of goiter, which could not always be explained as due to pressure, was considered as offering corroboration to this theory. It is probable that the increased respiratory movements observed in thyroid diseases and in thyroidectomized animals are due to the fact alluded to previously, that the gas exchange is so altered that the oxygen standard is reduced to below normal, so producing an asphyxiated condition of the respiratory center, and resulting in a stimulation of the respiratory muscles. That this is the probable explanation has been demonstrated by Schiff, who was able to reduce these symptoms by artificial oxygenation of the blood. The increase in size can readily be explained by the increased blood pressure that is always produced by the high intra-thoracic pressure during forced respiration.

In confirmation of the ninth theory we have the experiments of Horsley, who found that in thyroidectomized monkeys the red blood corpuscles diminished steadily until they reached an oligemic equilibrium, which was maintained until death, and also that in the thyroid veins the leucocytes were more numerous than in the arteries passing to the gland, or in the vessels of the limbs. In regard to this last fact it is to be remembered that lymphatic tissue is constantly found in the thyroid, and often-times thymus rests. The anemic condition observed in athyreosis can be best explained by the theories to be described later. In the acini of the gland red corpuscles are often found imbedded in the colloid substance, but they seem to be in a state of degeneration, although Bozzi observes that they retain their form and size for a longer time than is usual in extravasated blood. The increase in mucin in the blood after removal of the thyroid, observed by Halliburton, is probably due indirectly to the thyroid through its effects on the connective tissues. The increased venosity before mentioned may be ascribed to a change in the respiratory function, or to a change in the chemic condition of the hemoglobin so that oxygen is less readily taken up.

As to the tenth theory there can be no doubt that the removal of the thyroid gland does increase the amount of mucin in the body, and it has been suggested that the gland forms some ferment which is able to break up the mucin into some other bodies, a lack of this ferment in myxedema causing an accumulation of mucin in the tissues. However, all attempts to isolate such a ferment from the gland have failed, and all attempts at demonstration of this theory have been unsuccessful.

It is a constant observation that the thyroid gland is greatly atrophied in advanced years, and on this the next theory is based. As was shown in the writer's cases the weight of the gland in people over 45 years of age was but two-thirds of what it was in those under that age. While this theory becomes absurd if we take it as meaning that if senile changes are due solely to a lessened capacity of the thyroid, one might escape old age forever by taking thyroid extract, yet it has some weight. In the first place perhaps the most serious change in senility is arterio-sclerosis, and a thickening of the intima very similar to that in the above pathologic condition has been described as occurring constantly in the vessels of the thyroid gland of young and healthy people. And again, the most marked changes observed in athyreosis are due to alterations in nutrition, in which function this organ seems to play a great part, and it is probable through failures in nutrition that the body reaches the wasted condition accompanying old age.

We now reach two theories that have grown out of exhaustive studies of the thyroid during the last few years, each with its advocates and much evidence in its favor. The first of these is in direct relation to the modern theories of auto-intoxication. It presumes that constantly during life the tissues are producing substances as a result of their metabolism, lower chemical forms derived from the complex proteid molecule and which accumulating in too large quantities through some failure of excretion, destruction or neutralization, are poisonous to the organism and produce symptoms of various kinds. With these substances may possibly be included toxic materials produced by fermentative processes in the alimentary canal and taken into the system. To meet these undesirable materials it is presumed that the gland produces the thyroiodin which is circulated through the system and meeting the toxic substances as soon as formed neutralizes them, perhaps by causing their decomposition in a ferment-like manner, perhaps by uniting with them and producing innocuous compounds. It is very easy to imagine the thyroiodin playing such a role as this, especially when we consider the general precipitating action of iodin on all alkaloids and alkaloid-like bodies, in which condition we generally consider the toxic substances as existing in the body. Or again it may be supposed that this action merely occurs in the cells of the gland itself while the blood is circulating through it, and independently of any true secretory action. The gland failing in the performance of its function, these noxious substances accumulate until they cause disturbances in the organism, resulting in the condition known as athyreosis. In confirmation of this view it has been shown that if the blood of an animal suffering the symptoms following thyroidectomy be injected in another animal, especially if it has previously had its own thyroid removed, that it is toxic to this second animal and all the classical symptoms of athyreosis are immediately produced even if there were no indications of them previously. On the other hand we have the effect of thyroid extract on blood pressure, which is unquestionably due to a specific effect of the extract itself since it is produced in animals having a perfectly healthy and active thyroid, and so can not be attributed to any neutralization of other substances. However it may be that this action is due to the extractives of the gland outside of its fundamental principle, Schäfer having used ordinary glycerin and aqueous extracts in his experiments upon this point. Still it seems to the writer that the symptoms of thyroid deprivation are of too definite a nature to be produced by the action of the tissue toxins which must necessarily, judging from our knowledge of the complexity of the chemistry of cell metabolism, be many and varied. And again the manifestations of myxedema and cretinism, and the athyreotic conditions generally seem to reach a certain degree of intensity and there remain, rather than progress as one would expect from a constant accumulation of the substances causing them, which must occur if they be non-neutralized products of tissue metabolism. It might be argued that some other organ takes up the role of the absent or functionless thyroid adventitiously after these conditions reach a certain intensity, yet if such be the case why does it not entirely obviate them, or why do they so often progress even to a fatal termination without compensation.

The second of these last two theories is entirely different from the first. for it relates to the conditions producing normal metabolism and entirely disregards the noxious products of cell activity. It suggests that for the proper performance of their function the cells must receive in addition to the ordinary food materials carried in the blood and with which we are familiar, a certain body or bodies without which their action is perverted or abortive, just as it is necessary for the production of a clot that calcium salts be present. As a result of this in the young and developing animal when the cells fail to receive their full complement of thyroiodin, if this be the essential substance, some of them, at least, do not multiply exactly as they would have done otherwise, and we get the condition seen in cretinism. Similarly in the adult the connective tissue cells in their reproduction do not get beyond the embryonal or myxomatous condition, and the tissues are left as we see them in myxedema. Following out the same line of reasoning the increased amount of excretion by the urine and the dimunition in the weight of fleshy subjects can be explained by the statement that not only is the thyroid principle necessary to metabolism, but an increased supply results in an increase in metabolism, which naturally causes the described changes. And further this overstimulation results eventually in the palpitation of the heart and the other symptoms accompanying it, while a lack of stimulation produces a lessened or altered nervous activity with the changes resulting therefrom, notably the ultimate loss of sensation and control of voluntary motion, as well as the failure of the thermotaxic apparatus. While it must be admitted that the last statements are rather broad, still they are hard to gainsay, and they serve well to cover the ground until further experiments give us more definite information. It must also be mentioned that they do not explain the vaso-dilator effect, which would seem to be too rapid and transitory to be the result of cell metabolism. Neither is the change in the ability of the blood to exchange oxygen for carbon dioxid explained satisfactorily by this theory.

Acting on the basis of the last two theories we can consider that the changes observed in the thyroid gland during pregnancy, at menstruation, etc., are due to hyperactivity in an attempt either to neutralize an unusual amount of toxic substances or to furnish the stimulus necessary for a general increase in metabolism occurring at this time. They explain the changes in the blood in athyreosis as due to the destruction of its elements by poisons, or to a lessened activity in the blood-forming tissues. The myxomatous condition can be ascribed to Semon's theory of incomplete metabolic changes or to a mucoid degeneration due to saturation of the tissues with the injurious products of metabolism. So it is apparent that one may work from either theory and explain the facts upon which all the others are based, and still leave it an open question as to which of the accepted hypotheses is the nearer correct.

Therapeutics.—In the beginning of this article the history of the therapeutic use of the thyroid was followed up to the time that Mackenzie and Fox introduced the method of administration, by the mouth, of gland extracts or of the gland itself. At this time the the practitioner in treating a case with the thyroid was obliged to rely on the nearest butcher for glands which were given to the patient fresh, partly cooked, or a glycerin extract was made that could be kept for a short time. Soon it was found that the glands could be desiccated and a powder made which retained the full activity of the gland, and from this it was but a step to the preparation and marketing of tablets made from the desiccated glands, in which form it is now almost exclusively used, in this country at least, on account of the greater convenience. The great disadvantage of the tablets is their extreme variation in activity, since by chemic analysis it is seen that one gland may contain in an equal bulk fully five times as much of the active principle as another. Also there is the ingestion of the residual animal material, of which there is no gaurantee as to purity or freedom from disease germs, since to prevent injury to the active principle the gland is not heated to over 30 or 35 degrees C., in the preparation of the tablets. To obviate these defects preparations of the thyroiodin itself in the form of a milk sugar triturate are now produced, and have been quite widely used in Germany. This permits accuracy in the dosage and does not require the administration of doubtful extraneous materials along with the drug, while all the effects of the other preparations seem to be obtained.

The ordinary dose is from one to three tablets, each representing five grains of the gland. A few large doses seem to have no bad effect, a case having been reported where a child two and one-half years old took at one time ninety tablets without any noticeable effects. Buschan took, in a short time, 250 tablets, up to twenty a day, and noticed only slight symptoms of the heart and diuresis. If the large doses are continued, however, there will appear serious symptoms, the most marked of which are palpitation of the heart and headache, nor do they seem to have more effect upon the diseased conditions than do the ordinary doses, which do not generally produce subjective symptoms. During the administration considerable diuresis and a loss of weight without impairment of strength and vigor are generally noticed. The thyroiodin is apparently absorbed as such, and produces its effects very quickly, indications of its action being often observed in a few hours. What its ultimate destination and fate may be are unknown. The statement of Roos, that the thyroiodin acts more rapidly when administered in the free state than do the extracts, is not borne out by clinical experience.

The conditions in which the thyroid therapy has met its greatest successes are naturally the two athyreotic diseases, myxedema and cretinism. At first the thyroid extract was exhibited only in these two affections, but as more was learned of its effects its use was extended until now there is hardly a diseased condition in which it has not been tried and, as with every new remedy, it has at least a few advocates for its use in each of them. Only those diseases, however, in which there is some logical reason for its use or in which it has met with a certain degree of success, will be considered, and they will be taken up approximately in the order of their value of this method of treatment.

Myxedema.—The relation of this disease to the thyroid gland was first pointed out by Ord in 1878, and its identity with the condition resulting from operative removal of the thyroid was shown by Reverdin in 1883. The experimental production of the same symptoms in animals and their prevention by transplantation of glands into other parts of the body by Schiff and Horsley led to the suggestion by the latter, in 1890, that sheep's thyroids be transplanted into people with this disease, and was the beginning of thyroid therapy. As myxedema is due simply to a lack of thyroid secretion, because of an atrophy of the gland, varying from a marked reduction in size to a complete replacement of the secreting structures by fibrous tissue, the administration of thyroid extract produces an absolutely certain cure. If the disease is correctly diagnosed and an active preparation of the gland used, there can be but this one result. Since, however, the gland can not be restored to its normal condition the cure lasts only as long as the remedy is being administered. Therefore the treatment is in two stages: In the first the dose is large—up to ten or fifteen grains per day, until the patient reaches a normal condition; the second consists in the administration of smaller doses at regular intervals to prevent the return of the symptoms, the amount necessary varying with different cases, but this can be determined in a short time by the reduction of the dose until the minimum amount is ascertained, generally one or two five-grain tablets a week being sufficient. If in the first stage of the treatment the dose is pushed too high, it will be shown by the appearance of palpitation of the heart, headache, itching of the skin, and sometimes even delirium and spasms are produced. All these symptoms can be obviated by diminishing the dose.

Under this treatment the swelling of the skin disappears, and it becomes moist, soft and flexible. The pulse rate increases, there is a return of vigor, and the patient loses the mental torpor and apathy. All these changes occur to completion in a few weeks, and improvement is often noticed in twenty-four hours. Occasionally glycosuria and albuminuria have been noticed during the treatment, but these cases are not common and the condition is usually transitory. Serious effects are sometimes produced in cases where heart lesions already existed, two or three patients having died while under the treatment, and in such cases great care must be taken to avoid overdosing.

Cretinism.—This disease is fortunately very rare in the United States. Osler, in 1893, was able to collect but eleven well authenticated cases occurring in this country, but since that time, on account of the general interest in this disease because of its connection with and cure by the thyroid gland, many more have been reported. One occurring in Chicago was reported a year ago by Dr. J. B. Herrick, and Dr. D. L. Shaw has now a case in his practice. Since cretinism is a congenital athyreosis, the cure by the thyroid extract is just as certain as in myxedema, while the changes are even more marked. A dwarfed, misshapen, repulsive creature, devoid of intellect, and but a source of disgust and care to those about him, is transformed in a few weeks or months, at the most, to a child with at least ordinary sightliness, which runs about and plays with as much vivacity and vigor as any of its mates—one of the lowest forms of animal existence has been changed to a human being. This power of the drug alone entitles it to a place among the specifics. However, it is not probable that the cure in these cases will often be complete, since, as a usual thing, before the trouble is recognized changes have taken place in the skeletal and cerebral structures that can not be fully repaired; but nevertheless the treatment is of inestimable value and it may be that some means of early diagnosis may make possible perfect results. As in myxedema the treatment must be continued throughout the life of the individual. Fortunately there is no such thing as an acquired tolerance of the drug, Murray's original patient being now living in good health, but still taking the thyroid.

Simple Goiter.—The writer has collected, from the literature, 584 cases of simple goiter treated with the thyroid extract, and of these, 475 or about 82 per cent. have been improved. Bruns, who has treated about 350 cases in this manner, sums up the results as follows:

1. The greater proportion of goiters are amenable to treatment with the thyroid, both the swelling and accompanying troubles being relieved. Only about one-fourth remain uninfluenced.

2. A complete cure of goiter only occurs in about 8 per cent. of the cases: in one third there is a considerable decrease in the swelli [illegible]

obviation of the symptoms; and in another third there is only a moderate diminution.

3. Age has great influence, the beneficial results being greatest in children and diminishing with age. The less time the goiter has existed the sooner its cure is resulted.

4. Immediately on administration the results begin to appear, and after four to six days the size of the neck is measurably diminished, and the breathing freer. In 300 cases the diminution was reached in two weeks in 60 per cent.; in 40 per cent. after three or four weeks.

5. Of the different forms of goiter only one, the simple hyperplastic struma, is accessible to this treatment, but here the action is certain and prompt.

6. In more than three fourths of the cases, after stopping the treatment the goiter again grows, generally beginning in from one to four months after the cessation. However, small doses at stated intervals are sufficient to prevent the recurrence.

The improvement in simple hyperplastic goiters is explained readily enough if we consider that the hypertrophy is simply an attempt on the part of the gland to meet an increased demand from the system for thyroiodin. This increased demand may be considered as due, either to some change in the metabolism of the body requiring an unusual amount of thyroiodin, or to a deficiency in the supply of iodin brought to the body by the food and drink, which requires unusual activity on the part of the gland to accumulate enough iodin from the blood to produce thyroiodin for the requirements of the organism. Whichever is the case the object is apparently attained, for in ordinary goiter there are no symptoms due to lack of gland secretion. If the first of these suppositions is correct we would expect that the gland would contain an increased amount of iodin, although the amount in each gram would not necessarily be increased over the normal. In the second case we would expect to find the total amount for the enlarged gland very much the same as in a normal gland, and therefore the amount in each gram would be much below the normal.

Baumann found, in a series of twelve cases of goiter in which the average dry weight was 32 grams, that the total amount of iodin in each gram was but 0.09 mg., which gave as a total 2.6 mg. of iodin to each gland, or practically the same as he had found to be the usual amount in Freiburg glands. These results, therefore, point to the second of these hypotheses as being more probably correct. The writer has analyzed a smaller number of glands, which, however, have led to different conclusions, namely: That goiters due to a simple increase in the gland tissue, so that they consist structurally of masses and strings of cells or epithelial lined vesicles, which may or may not contain colloid (struma hyperplastica parenchymatosa), do agree with the second hypothesis; but that colloid goiters in which the increase in size is due to a production of colloid-filled spaces with little inter-vesicular tissue, agrees with the first hypothesis. These conclusions are based on the analysis of five goitrous glands.

Two were of the hyperplastic variety, consisting structurally of masses of tubules closely packed together, with few colloid-containing vesicles, and many masses of epithelial cells with no definite arrangement, together with a considerable increase in the connective tissue. Of these:

No. 1 was from a woman of German birth, 69 years of age, a resident of this country for twenty years. The dried gland weighed 27.07 grams, each gram containing 0.304 mg. of iodin, which gives as a total 8.23 mg. of iodin. No. 2 was from a man, 40 years old, of Irish birth, but probably a resident of this country for many years. The dry gland weighed 16.24 grams, contained 0.511 mg. of iodin in each gram, with a total amount of 8.3 mg. in the entire gland. Both of these results are close to the average amount found in normal glands in this country, while the amount in each gram is in one case but one-fourth, in the other but one-sixth the normal proportion.

Two others were diffuse colloid goiters, consisting throughout their entire substance of greatly dilated vesicles lined with flattened epithelium and distended with colloid. No. 1, from a woman, recently come to this country from Bohemia. The gland weighed 13.19 grams, each gram contained 4.03 mg. of iodin, the total amount being 53.16 mg. No. 2, from a woman of English birth, 30 years of age, whose dried gland weighed 12.42 grams, each gram containing 1.98 mg., the total content being 24.59 mg. of iodin. These glands would seem to indicate, therefore, that the proportion of iodin in colloid goiters is at least as high as normal with the result that the total amount is very large. This is especially well shown by the fifth gland, which was also from a Bohemian woman, and which contained a nodule that was composed of tissue nearly identical with the colloid goiters in structure, but which seemed to be a benign neoplasm. This nodule was surrounded by a distinct fibrous capsule, so that it could be removed without disturbing the rest of the gland, and it was then analyzed separately. The nodule was found to contain in each gram 1.98 mg. of iodin, while the remainder of the gland contained but 0.8 mg. in each gram. The total amount in the entire gland was 9.26 mg., or about the normal quantity. Therefore it would seem that the colloid new growth had so met the demands of the body, that the remainder of the gland had lessened its activity in proportion.

The writer would also call attention to the fact that Baumann found two goiters containing large amounts of iodin in his series; in one there was 17.5 mg., in the other 31.5 mg., which are especially large quantities when compared with the low normal content of the German glands. It seems very probable these were colloid goiters. Since the number of goiters available to the writer was so small, the statements based on the results of these investigations are not made as positive, further than that they agree with the facts at hand. The possibilty that more statistics may show these cases to have been exceptional is fully appreciated.

An interesting suggestion coming from the analyses of the goitrous glands is, that not only does the normal American gland contain a much greater amount of iodin than does the German gland, but also that this amount is necessary to inhabitants of this country, so that the gland will hypertrophy to keep the iodin content up to the standard, as shown in the first two goiters.

(To be continued.)

Inconveniences of Airol in the Treatment of Soft Chancre.—O. Goldfarb reports several patients treated with airol for soft chancres, on whom it produced blisters, etc., resembling a burn of the second degree.—*Semaine Méd.*, August 11.

SURGERY ONE HUNDRED YEARS AGO.

AN HISTORICAL STUDY

BY DR. GEORGE FISCHER.

TRANSLATED FOR THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION BY CARL H. VON KLEIN, A.M., M.D.

XV.—DISEASES OF THE BONES, JOINTS AND MUSCLES.

(Continued from page 911.)

As to the diseases of the muscles, we emphasize that after W. Cooper (in 1694) first described a *muscular luxation* of the long head of the biceps, Bromfield and Pouteau likewise mentioned it, but the symptoms collected do not make the diagnosis sufficiently certain. It is evident that hitherto no verifying postmortems for isolated dislocation of the biceps tendon, not combined with luxation of the ball of the joint, are at hand. One saw *muscular lacations* of the biceps completely healed (Duchenim, 1786). J. L. Petit has noticed a case of *rupture of the tendon of Achilles* of a juggler, who in an attempt to jump upon a high table with both feet at once sustained this injury of both tendons. For the treatment, wherein the principal point lies in extending the foot and bending the knee, he and Ravaton constructed so-called slippers. Perhaps the circumstance that two so illustrious men as J. Hunter and Alexander Monro, senior, each suffered a laceration of this tendon contributed to the fact that the injury hitherto little known became a veritable mine of inventions of new bandages. (Our time experienced something similar when Garibaldi's injury to his foot drew after it every possible and impossible invention.) Hunter condemned the exaggerated carefulness of treatment, but fell into the opposite error when after a few days he arose and went about with a shoe which had a high heel; in his case the intersubstance is said to have become ossified. As regards bandages, we notice that Monro left the point of the slipper open in order not to hurt the toes. Just on this account and because after healing, walking in the slippers was difficult for the patient, Desault invented a new bandage; he placed at the back of the limb a long compress reaching from the foot to above the knee-joint, filled out the hollows at the sides of the tendon with graduated compresses and made a circular envelopment from the joint of the foot to the knee. Wardenburg modified this bandage and had hollow splints of metal adjusted to the knee and ankle-joints. Richter recommended his pupil's method, when one could not by the position of the limb alone, always the best treatment, bring about a contact of the ends of the tendon. Very simple, too, was Schneider's bandage, which bound the leg, with the foot extended as much as possible, to a hollow splint reaching from the toes to the knee (1787). The suture of the tendon recommended by Heister, Garengest and others was soon discarded on account of inflammation and suppuration of the tendon and of the tearing out of the suture (Richter). Acrel reported a cure by this method, but after a few years the tendon tore apart again in the same place by a quick upward step.

Caput obstipum was supposed to arise from scars, the contraction of the sterno-cleido-mastoid muscle in consequence of a metastasis of an irritating morbid matter to the clavical muscles or from paralysis of them, or muscular cramp. It is well known that today a few surgeons deny the so-called congenital form, which is said to arise only from the laceration of the sterno-cleido-mastoid at birth. On the other hand, it is to be remembered that Bündell, in the year 1762 (R. A. Vogels "Neue med. Bibl.," V. Bd., S. 189), demonstrated as the cause, at that time still unknown, of congenital caput obstipum, "that the M. mastoideus upon one side was only a tendon," and Hensinger (1839) found the contracted sternal portion of a child a few days old, was composed not of muscle substance but of white tendinous tissue. Only the wry-neck from muscular contraction demands an operation, when the internal and external application of anti-dyscrasia remedies are without avail (Richter). Shard deserves the credit for the method of operation; he had the sterno-cleido-mastoid strained, cut across the skin, inserted under the muscle a probing knife devised by himself and severed the muscle from within outward. His treatment was the most used until the time of the subcutaneous methed. B. Bell, for fear of injuring the vessels and nerves, advised separating the muscle gradually by small incisions from without inward. As a rule the separation of the sternal portion satisfied Richter, who considered an inch above the sternum as the best place for the incision, but he also cut through the clavicular portion if it was strained, and afterward held the head straight by means of bandages until the wound was healed. For that purpose a leather cap, devised by Köhler of Jena, was very much used (1796). It has been previously mentioned that Gooch first observed a wry-neck caused by the contraction of the platysma myoides, which he cured by cutting the entire breadth of this muscle underneath the skin (1759).

Orthopedia as a science was born in the eighteenth century and was first cultivated upon Swiss and German soil. They who claim a French origin for it because Andry, the originator of the word orthopedia, published the work "L'orthopédie ou l'art de prevénir et de corriger dans les enfants les deformités du corps" (Paris, 1741), should reflect that in this work many other diseases, as chilblains, harelip, red nose and itch, are treated. Crooked limbs were regarded by the great mass of surgeons as incurable; the patients were left to the physicians of the Jahrmarkt and so-called "regulators" (Einrichter). *Johann Andreas Venel* (1740–1791) of Yverdun came forward to dedicate himself entirely to this neglected branch of surgery. The successful cure of a clubfoot induced him in his 39th year to go to Montpellier for the second time, in order to study anatomy again. He then had a hospital of his own built, where in special work-rooms in connection with it, apparatus and bandages were prepared under his supervision. Soon the number of his patients grew, and they came to him from Switzerland, Germany and other countries; but he accepted only children who had not passed their eighth year, and treated their curvatures of the feet and knees, and probably also of the spine. At their entrance, and again after they were fully cured, he made in each case a plaster cast of the deformed limb and published drawings upon eight plates. Within twelve years of tireless activity, during which he had to contend against poverty, misfortune and many difficulties, he accomplished about a hundred successful cures; his method was about to be made public when he died. Dr. Ehrmann of Frankfort on the Main was the first who imitated Venel's treatment in Germany, and he imparted it to Brückner of Gotha, [illegible] then like[illegible] took up this specialty and published a work on it ("Ueber die Natur, Ursachen und Behandlung der einwärts gekrümmten Füsse oder der sog. Klumpfüsse," Gotha, 1796). The works following, by the two Germans Naumburg and Wanzel, were unimportant, while abroad, Sheldrake (1794) and especially Scarpa ("Mem. chir. sui piedi torti congeniti dei fanciulli." Pavia, 1803) deserved some credit for their work on clubfoot. Portal's work ("Obs. sur la nature et la traitement der Rachitisme, ou des courbures de la colonne vertébrale et de celles des extrémités," Paris, 1797), and in Germany Feiler's work ("De spinæ dorsi curvationibus," Altdorf, 1798), were of importance for curvatures of the spine. Orthopedics was wrested from the quacks and elevated to an independent surgical doctrine.

It was known that clubfoot was as a rule congenital, and the cause was supposed to be an unnatural position of the foot in the uterus, it being pressed inward, which resulted in a contraction of the m. tibialis ant. and post. and of the gastrocnemius. It is well known that Eschricht (1851) first taught that that position of the fetus was not unnatural and that congenital clubfoot could be explained as the persistence of the normal curvature of the fetus at a certain stage. To correct the contraction was the object of the treatment, which offered a better prospect of success the earlier after birth it was undertaken. In order to relax and distend the muscles, the German surgeons, according to the example of Brückner, first had emollient remedies rubbed in, gave foot-baths and continually kneaded and stretched the foot with the hand according to prescribed manipulations, but never allowed the patient to walk on his feet. Only when after a few weeks a greater flexibility was reported, were bandages or apparatus applied and that treatment continued. Among the great mass of newly invented appliances those of Cheselden, White, Van der Haar, Bell, Brünninghausen and others, were the best known. Venel's sabot and Brückner's boot were the two principal types of apparatus for clubfoot and were older than Scarpa's boot, which has become celebrated. For newborn children they were usually satisfied with Brückner's bandage. When walking was again permitted they had the patient wear a laced boot which reached to the middle of the lower part of the thigh and had no heel, but a heel-cap of stiff leather. The most important advancement was due to the German physician Thilenius, who in 1781, in the case of a clubfoot of a girl 17 years old, which neither bandages nor apparatus helped, in spite of the traditions of antiquity as to the danger of tendinal wounds, showed the great courage to have, for the first time, the tendon of Achilles severed, after it had been laid bare and made free by an extensive cut. He was not understood by his contemporaries. Even in the year 1792, C. C. von Siebold regarded the straightening of a clubfoot by severing the ligaments and tendons as dangerous to life on account of gangrene and caries; and he recalled with horror how a country surgeon had the knife in his hand, ready to straighten the foot of a newborn baby!

XVI. DISEASES OF THE BLOOD VESSELS, NERVES AND SKIN. NEOPLASMS.

Aneurysms; Phlebitis, wounds of the veins; Lymphangitis; Anæsthetics; Tetanus, compression of the carotid, facial pains; Ulcers; Furuncle, carbuncles, erysipelas; Burns, chilblains, whitlow; Warts, corns; Neoplasms, scirrhus and cancers; Breast, lip and chimney sweep's cancer; Encysted tumors; Ganglion, teleangiectasis.

If, in Germany, nature was sparing of *aneurysms*, yet art replaced this lack with sufficiency by the lancet of the barbers and of the barber journeymen. Within five months four cases of aneurysm from blood-letting came under the treatment of Professor Leber of Vienna. There existed at that time great confusion in nomenclature, as is the case even yet to some extent; they threw true and false aneurysms together promiscuously. While a few called the aneurysm arising from a blood-letting a true aneurysm (Leber and Plenk), others applied this designation only when the sac consisted of strong annular muscle fibers (A. Monro); again, others called the cylindric form, caused by the distension of the entire arterial wall, a true aneurysm, and, on the other hand, called the sac formation, which arises from the laceration of the inner membrane and the distension of the outer, a false aneurysm (Morgagni). In Germany those classifications were the most current which came from England, the country in which aneurysms were most frequent, where the two Hunters, D. Monro and J. Bell devoted themselves especially to this disease. In the second half of the century, they designated those swellings in which the artery was at any place unnaturally enlarged or distended as aneur. verum, and distinguished them as aneur. verum circumspectum and diffusum, according as the distension was found in only a small place or to a greater length of the artery. On the other hand, the swelling in which the blood entered the cellular tissue through an unnatural opening of the artery, and, as Heister would say, flowed between the skin and the flesh and formed a sac there, was named aneur. spurium. Donald Monro applied this name especially to the traumatic hematoma of the present day. The false aneurysm was also either circumspect or diffuse, and was most excellently described by John Bell. As a third main division, Hunter introduced the aneur. mixtum, in which the external coat of the artery was lacerated by an injury and the internal uninjured coat was in consequence distended as a sac through the opening (an. mixt. int.), or *vice versa;* after laceration of the inner coat, the outer is enlarged (an. mixt. ext.) The first form was later declared to be impossible, as J. Hunter's experiments had demonstrated that the inner coat does not bulge out after the removal of the outer. He had removed the outer and a part of the other coats of the carotid and crural in dogs, so that through the thin walls one could clearly see the blood as it flowed; but the artery was never distended. An an. mixtum was also supposed to arise from the bursting of a true aneurysm. W. Hunter discovered (1762) the communication between arteries and veins resulting from blood-letting; *in this way the anterior wall of the vein* is closed while the *posterior* wall and the wound in the artery remain open, so that the arterial blood presses into the vein and distends it. He named this, varix aneurysmaticus. Park described an aneurysm from blood-letting, as large as the fist, in the bottom of which he found, after opening the sac, an orifice into which he inserted a probe to the depth of an inch, but could move it neither upward nor further downward. The orifice led *into a small sac*, the size of a nutmeg; lying underneath, and at the bottom of this sac, was an aperture through which one could penetrate into the artery. After that these swellings were separated into kinds, the aneur. varicosum and the varix aneurysmaticus. The confusion became greater when W. Hunter, to some extent, confounded the so-called an. cirsoideum with those two forms, and a few surgeons began to designate them as an. per anastomosin. J. Bell gave this name only to those blood tumors, which, distinct from congenital teleangiectasis, in consequence of an injury, arise from the enlargement of previously existing anastomosis of smaller arteries and veins. Finally, in the beginning of the century, Scarpa threw them all aside and declared that there is no true aneurysm in the old sense, since none ever arises from an equal extension of all the arterial coats, but from the destruction of the inner and middle coats and the escape of arterial blood into the cellular sheath or tissue enveloping the artery. A weakness of the arterial wall, as a result of bruising, sudden wrenching, or forcible movements, or most frequently a disease of the arterial system, were regarded as the causes of true aneurysms. A. Monro, senior, knew the bony and stony concretions of the inner coat very well, and considered them a frequent cause of arterial disease. Donald Monro also often found all the arteries extraordinarily fragile and brittle; sometimes, on the other hand, unnaturally hard, almost bony (1771), and Baillie observed frequent ossifications with increasing years (1793); but no one saw clearly the atheromatic process as the cause of aneurysms. They believed, indeed, in a general cause, because sometimes several swellings appeared at the same time on various parts of the body; for example, Donald Monro saw on one patient four aneurysms on the right arteria cruralis and two on the left. Our forefathers described the symptoms very accurately. Donald Monro advised against feeling of the swelling too often and too vigorously in examination, because in so doing one might easily loosen a bit of coagulated blood, which, being carried away, might occasion an obstruction in one of the other arteries, whereupon unexpected conditions might ensue. What Monro wished to avoid, Ferguson in our day recommends in treatment; but his kneading method has had no success on account of its danger. Ford and Desault described spontaneous healing. The latter had decided to operate in a case of true aneurysm of the popliteal when he suddenly noticed that the swelling had diminished about two-thirds in twenty-four hours, no longer pulsated, and had become quite hard, while above the swelling the cruralis with the side branches pulsated much more strongly. When the patient died of apoplexy they found the arteria poplitea, close above the aneurysm for a length of three inches and also below it as far as the division in the tibialis, was entirely obstructed by a clot of blood. According to Heister, false aneurysms gave a worse prognosis than the true, and he regarded aneurysms of the carotid, subclavian, axillary and of the crural near the trunk as incurable, because in an operation for them one could not stop the blood and had to fear inflammation.

In the first half of the century the treatment was mainly directed to the size of the swelling. Besides Valsalva's method, which was supplemented with local applications of ice (first mentioned by Donald Monro), they recommended compression for the small swellings and incisions for the large ones. The compression was at that time direct. Heister constructed a truss-like instrument, whose pelotte was pressed against the swelling by means of a screw. This was supplanted by the compressorium of the Berlin physician, Senff, which consisted of a cushion of a doubly decussated feathers and found many applications (Platner, Richter and Acrel). The number of compressoria and compression bandages grew to infinity, but they added nothing to the favorable results. Then there appeared as the next advancement the indirect compression, which, as a rule, was applied together with direct compression, but was not yet applied by itself. It came from the German surgeons.

History unjustly ascribes the priority in the introduction of indirect compression to Guattani (1772). but in the year 1770 Leber made public some cures by compression in connection with indirect. He laid a hollowed cork on the swelling and pressed together the upper part of the artery by graduated compresses. Theden, moreover, made public his methodic envelopment of the whole limb, with long narrow compresses the thickness of a finger, on the trunk of the artery (1771), and in this way he cured traumatic aneurysms. These German observations were known, therefore, two years before Guattani's work appeared. To him direct compression on the swelling was the main point, and he used the indirect in the form of long narrow compresses and bandages only as a means to weaken the pressure of blood at the swelling. Leber also deserves the priority in attempting indirect compression alone, without direct, although his treatment failed in the case of an aneurysm from blood-letting, and he did not properly estimate the value of this method. The honor should remain with Desault of having first attempted indirect compression alone in a case of "true" aneurysm (1785), when, according to Camper's clever idea, he compressed the subclavian against the clavicle, in a case of aneur. of the axillaris; the patient would not submit to a continuance of the treatment. J. Hunter first accomplished a cure (as E. Home related in 1793) by means of indirect compression in the case of an aneurysm of the cruralis in the middle of the leg, by the application of a tourniquet to the artery a little below the lig. Poupartii. The pressure became so painful that the instrument had to be taken away, but after threatened inflammation and swelling of the aneurysm the pulsations ceased and the sac became quite small and hard. Hunter, indeed, seemed to have some curiosity to further prove indirect compression, but as in the next case also the pressure caused by the tourniquet could not be borne, he discarded the method. Then Brückner of Gotha accomplished a cure (1797) with indirect compression, in a very large true aneurysm of the popliteal, in the belief that this treatment was the principal remedy. He used an annular tourniquet; laid on the other side of the limb a long, stiff splint, and carried the compression of the art. femoralis only so far that the pulsations in the sac became weaker but did not entirely cease. (My historic notice in the Deutschen Klinik, 1868, Nr. 13.)

The methods of operating for true aneurysms consisted almost universally in the splitting of the sac with a double ligature (Antyllus) or in extirpation after the trunk of the artery had been fastened above and below the swelling. These old operations were for the most part fatal, insomuch that many surgeons abandoned them and amputated the limb (J. L. Petit), a passage out of the rain into the gutter. The idea of using the ligature for its own sake, without opening the sac, was an extraordinary advancement. It arose in Paré's time; for his pupil, Guillemeau, wrote as early as 1649, "Si en quelques autres parties extérieures il se présente au chirurgien pareil aneurysme, il peut seurement découvrir le corps de l'artère vers sa racine et partie supérieure, et la lier de mesme façon sans autre cérémonie." Anel made the earliest known operation of this kind on Jan. 30, 1710, in an aneurysm of the elbow curve, in which he bound the art. brachialis tightly above the sac. What were his thanks? His colleagues attacked him bitterly, and ascribed the cure to accident. Seventy years passed before Anel's idea came to the front. In the year 1781 Assalini saw this operation performed by the physician and surgeon of the Duke of Modena, Hercules van Este Spezzani. Desault convinced himself, by injections and experiments upon animals, that a ligature of the femoralis does not disturb the circulation in the lower parts of the limb, and in June, 1785, in an aneurysm of the popliteal he bound the femoralis close under the fork of the abductor magnus with success. But John Hunter first taught the true value of this operation. He also had formerly applied ligatures above and below the sac, and observed that death always resulted through hemorrhage or suppuration. Indeed, in September, 1785, he declared a thigh aneurysm of the size of an orange as not amenable to operation. Nevertheless, on December 12, he accomplished, whether with or without the knowledge of Desault's success, can not now be readily decided, his first celebrated ligature, which, instead of being applied close above the aneurysm, according to Anel's method, was placed at a greater distance from the sac. In view of the fact that the artery in the neighborhood of the sac was diseased, so that the threads of the ligature might easily cut through it at this point and cause a fresh hemorrhage, he bound the artery higher up, where it was presumably healthy, and the cutting through of the thread therefore not so much to be feared. It appeared to him sufficient to merely retard the flow of arterial blood by means of the ligature and by a gradual narrowing of the passage of the artery to moderate the flow of the blood toward the point of ligature whereby the blood in the sac coagulated and the sac shriveled up. Therefore he considered it unnecessary to open or to extirpate it. Hunter operated on a large aneurysm of the poplitea in the following manner: He made an incision into the front and inner side of the upper thigh somewhat above the middle, obliquely over the inner wall of the sartorious, laid bare the artery, isolated it with the spatula, introduced four threads under it, and so bound it in four places separated a little way from each other. Of these so-called reserve ligatures he bound up the thread farthest from the heart entirely tight: the one nearest to the heart remained lying under the artery as loose threads; the two other threads, as loose nooses, gradually narrowed the arterial passage. In case suppuration cut through the actual ligature too soon the loose threads should serve to quickly close the bleeding vessel again. The patient survived an after hemorrhage, and was cured only after seven months. This fortunate result convinced him that it was by no means entirely necessary to exclude arterial blood from the sac insomuch that he asked himself if the ligature was on the whole necessary, and if indirect compression would not suffice to keep the blood out of the sac until that remaining within it had been coagulated. He therefore undertook the above mentioned experiments in compression. He very quickly gave up the idea that it was better to bind the artery loosely in several places than strongly at a single point, and in his later operations always applied but one ligature, and drew it tightly together. He first recognized also the great importance of the coagulum in the sac which had hitherto been always regarded as an obstacle to healing and also the significance of collateral circulation. Hunter first established the principles of continuous ligature and introduced into practice his method of operation, which then, as today, bore his name, whereby, as Scarpa said, he erected an eternal monument to his renown.

In order to establish the method it was necesssary to demonstrate that the ligature of the trunk does not destroy the nourishment of the limb. Heister was very uncertain as to this point, and wished to have the question cleared up by dissections. Before the operation, compression of the main trunk was always recommended in order to drive the blood more into the collaterals to enlarge them, so that after the operation they could at once maintain the circulation in the limb (W. Hunter). This enlargement of the collaterals, by which sufficient blood was conveyed to the underlying parts, removed every danger from the stricture of the main trunk. They began to paint the great dangers of the old method of stricture according to Antyllus with vivid colors (Guattani and Deschamps), and Hunter's operation was soon copied by Blizard, Lyon, Birch and Cline. E. Home extolled it as very simple and safe, insomuch that it won the precedence over all other methods. At first Pott's authority stood somewhat in the way, unfortunately. Pott and also J. Hunter had observed that the artery almost always became diseased for a considerable distance above the sac, hence a ligature at that point is ineffective; he had also always observed a fatal result in operations according to Antyllus, and he regarded amputation as the only possibility of saving life, which Bromfield, on the contrary, opposed entirely. In the year 1786 Pott, in an aneurysm of the poplitea, made still another attempt to bind the artery on the posterior side of the thigh, and to the question as to what he would have done if he had found the artery diseased, he answered that in that case Hunter's method might perhaps be followed. But he could not easily decide to adopt this method because the oblique incision would sever most of the lymph vessels on the inner side of the thigh. Once he applied the ligature a very little distance above the sac, but the artery did not appear to be constricted at all, and he amputated the limb. Richter was cautious in his judgment of Hunter's operation. He did not comprehend the excellence of it; he could only condemn the four loosely applied ligatures as questionable, since Guattani had cured large aneurysms by direct pressure. In France, Hunter's reserve ligatures found favorable acceptance; Boyer and also Lisfranc applied four, sometimes even twice as many "ligatures d'attente." But Abernethy condemned this practice, since, in the multiplication of ligatures, one must separate the artery from its natural surrounding for too great a distance.

There remained certain large aneurysms (iliaca ext. and axillaris) in which a ligature above the sac, in short, every means of saving the patient, seemed impossible. Then Brasdor originated the ingenious idea of binding the artery just underneath the sac, leaving the latter itself, that the stagnating blood might coagulate and be absorbed, and the sac be obliterated. This operation, approved by Desault, Deschamps first performed (1798) in an aneurysm of the femoralis in the groin, but with fatal results. We can disregard the various other suggestions of that time for the cure of aneurysms, for example Lambert's arterial suture.

The discovery of *phlebitis* by John Hunter (1793) was the most important advancement in the realm of venous diseases. Could a vein become inflamed? The Germans theorized over this question *pro* and *contra.* Hitherto the doctrine, which even Z. Platner advanced, that venous inflammation could not occur, was accepted. His son first admitted (1793) that "the obstructions and inflammations, which it is believed are found in the arteries, as a rule, apparently have their seat in the veins. But he doubted whether in venous inflammation the blood exuded into the cellular tissue; when this is not observed, and, much more, when only the gorged blood vessels protrude, inflammation of the veins and not of the arteries is present." All empty froth; not a word of observations and dissection reports! Hunter taught that the inner coat might be the seat of inflammation and suppuration, especially in the larger veins, when, in case of severe inflammation of the cellular tissue, they run through the inflamed part, whether the inflammation arises spontaneously or after an injury. He could sometimes show actual accumulation of pus in the vein, and, after blood-letting, many small abscesses in the entire course of the vessel; in dissections the vein was frequently stuck together in several places and ulcerated. The result of large collections of pus is the obstruction of the vein. He believed that phlebitis was especially to be feared if the inner cavity of the vessel is exposed to the outer air, and he therefore advised, in bleeding, that the wound in the coat be well drawn together and covered with a compress. He distinguished an adhesive, suppurative and ulcerative phlebitis. The first form was said to proceed from the extravasation of coagulable lymph; in the second, pus arises in the inside of the blood vessel, which is mingled with coagulated components of the blood; in the last, abscesses are formed whose evacuation by the action of the heart is often prevented by adhesive inflammation. Large venous wounds were treated by pressure, or, if this was not sufficient, by stricture; this latter method was not avoided since the anastamosis maintained the circulation.

J. Hunter also described the symptoms of *lymphangitis* with the streaks running upward, the painful glandular swellings, chills, etc., and traced the phenomena to an irritation spreading along the lymph vessels. Theden groped in darkness, when, in his own case, after an injury, a "panaritium followed by boils on the inner condyle of the upper arm" developed, from which the pain became so great that he had almost determined upon amputation. He said that the disease was indeed very similar to a panaritium, "but was still something of another kind, and proceeded from an absorption of putrid matter." There was even some question as to lymphangitis with suppuration of the lymphatic glands.

As regards the *nerves*, we have already mentioned the experiments of the Göttingen surgeons, Arnemann and Michaelis, in regeneration of the nerves, and also the discovery of the motor and sensory nerves by Charles Bell. What the English surgeon first proved absolutely by striking physiologic experiments, the Frenchman, Pouteau, had previously anticipated (1783), in that, from the fact that with patients sometimes a part of the sensation is entirely lost while the power of movement is not affected, he concluded that there must be different nerves for the two functions. He thought that the sensory nerves proceed from the cerebrum, the motor nerves from the cerebellum.

For centuries opium has been given in order *to make surgical operations as painless as possible.* But it is not of much use if it is not given in very large doses; then it is injurious. An early propagation of anesthesia we find in a wonderful way in Spain, where the physician, Theodorico, afterward Bishop of Cervi, had already described it accurately (1498). The Spaniard, Don Juan Fragoso, gave the following directions (1581): Take the juice of henbane, cicuta, mandragora and poppy, saturate a new sponge with the mixture, let it dry in the sun, then soften it again with hot water and have the patient inhale the vapor until he falls asleep. To waken him, he must be made to inhale warm vinegar vapor. Hans von Gersdorf had already given similar directions (1540). To avoid the injury of opium, James Moore of London suggested (1784) that the main nerves be compressed by means of a tourniquet, which must continue half an hour, until complete insensibility ensues. His observations were not sufficiently convincing; the continued and unavoidable pressure upon the blood vessels was also feared, therefore his suggestion did not prevail.

(*To be continued.*)

PRACTICAL NOTES.

Turpentine in Scarlet Fever.—The announcement of the specific action of turpentine in mumps (p. 595 JOURNAL), is now supplemented by a communication from Pujador y Fauva stating that he has cured 120 cases of scarlet fever with turpentine, children and adults, who were out of doors before three weeks, and none showed traces of albumin in the urine. Several malignant cases, ataxic, were cured by two hypodermic injections of 1 gram of essence of turpentine.—*Gaz. Méd. de Liége,* September 2.

Improved Local Treatment of Tuberculous Laryngitis.—According to M. R. Botey, the following formula combines in one remedy the advantages of cauterizing with lactic acid and painting with phenicated glycerin. The laryngeal mucosa is first rendered anesthetic with a 10 per cent. solution of cocain and then touched with the mixture, commencing with a small amount of phenic and lactic acid in the glycerin, and gradually increasing until the following limit is reached: Phenic acid, 1 to 5 grams; lactic acid, 2 to 15 grams; neutral glycerin, 20 grams. For external use.—*Semaine Méd.,* August 11.

Treatment for Whooping Cough.—Leuriaux, who has made whooping cough a special study, has addressed a paper on the subject to the Paris Academy of Medicine. The result of his researches shows that the treatment should be purely local and antiseptic. He recommends nasopharyngeal insufflations of a powder composed of sulphate of quinin (1 parts), resorcin (1 part), and white powdered sugar (25 parts). Insufflations should be taken five or six times a day, *preferably after a fit of coughing.* The Academy referred the paper to a committee to study the question.

By Combining Eucain with Cocain we secure a valuable anesthetic with the advantages of both and none of the inconveniences of either, according to the *Journ. de Méd. de Paris* of September 12. Eucain is the methyl ether of methyl-benzo-tetramethyl-γ-oxypiperidin-carbonic acid, and is a white crystal substance soluble in water, alcohol, ether, chloroform and benzine; melts at 104 degrees C; is not decomposed by boiling like cocain. Its solutions are consequently not affected by sterilization. Its anesthetic action [illegible] more [illegible]ble than that of cocain, while it is not toxic. Its effect on the pulse is to retard it while cocain accelerates it. A good formula for the combination is: Hydrochlorate of eucain, hydrochlorate of cocain, aa 20 centigrams; boiled distilled water, 20 grams. For hypodermic injection 1 c.c.

Success of Dittel's Elastic Ligature for Hemorrhoidal Nodules.—Recovery followed in every one of the 269 cases that have been treated in Dittel's service; twelve days the average. No anesthesia is used except Schleich's local infiltration. The curved polypus forceps are guided by a finger of the left hand inserted into the rectum. By turning the forceps ninety degrees the nodule is brought up out of the anus and with the surrounding mucosa is then ligated with an elastic cord stretched to its utmost. The nodules lose their vitality in eight to ten days and drop off, leaving a clean granulating surface. The external anal skin must not be included in the ligature, as this is very painful.—*Memorabilien*, August 23.

To Arrest Inflammation Subsequent to Vaccination.—Dr. Clement Lucas writes to the *British Medical Journal* that the use of bovine lymph has, in his practice, been more often followed by sore arms than when he relied upon the arm-to-arm method. He believes that he has found an easy and safe method by which to stay the inflammation in short order. His recommendation is the following: "Should, then, the vaccination pustules on the twelfth or fourteenth day tend to become confluent, while the inflammatory areola tends to spread beyond the usual limits, the glands in the axilla to enlarge and the arm, perhaps, to become edematous, the author suggests that the area of the pustules should be powdered over with iodoform and a sterilized dry pad be applied to keep the powder in position and the pustules from friction. In this way the process is completely checked in twenty-four hours. The pustules dry into a cake, the redness subsides, the glands decrease and the edema of the arm rapidly disappears. This is in every way preferable to hot fomentations or antiseptic moist applications, which, apart from the difficulty of applying them to an infant, involve the healing of open wounds." The British practitioner still continues to make five insertions of the vaccine material, whether it be of bovine or human origin, a number of wounds that is seldom, if ever, made by an official American vaccinator. When the latter is persuaded that he is in possession of a bovine lymph of good quality he is ordinarily, at least in some parts of the country, content with a single and not large insertion-surface. Whether the British practitioner will readily recede from his old five-insertion method or not, we think it will be for the interest of himself and his clients to have this subject officially investigated by the very careful men who are now at work in endeavoring to replace arm-to-arm methods with the glycerinated calf lymph. Sir Richard Thorne-Thorne, M.D., and Dr. M. Copeman are the intelligent subcommittee of the Local Government Board who are conducting this part of the official investigation on vaccination. The special report of the former member, quite fully illustrated, is before us, as is also a summary of that report as published in the *Lancet*.

Chronic Urticaria Treated with Sodium Nitrite.—Last summer I was consulted by a young lady for a chronic urticaria, in whose case the urticarial development was pronounced, the itching was great and at times the patient was so tormented that ordinary amusements were completely out of the question. Wherever clothing fitted snugly or any pressure brought to bear there speedily arose the large wheals and welts which persisted for hours. This had been her experience in summer seasons for many years and none of the many measures undertaken had brought relief. I could discover no intrinsic cause for the condition and knowing that much had been tried, I felt justified in attempting an experimental remedy. Regarding urticaria as an angioneurosis, I prescribed sodium nitrite in small doses, one grain three times daily. I was gratified the following day to be assured by the patient that she had experienced her first complete relief from the difficulty. And so through several weeks of hot weather, in which season she had been particularly subject to the difficulty, there was practically complete freedom from the annoyance before experienced, provided the remedy was continued in occasional doses. If it was discontinued for any period of time, the urticarial development would promptly reappear. Encouraged by this case, I took occasion to give the same remedy a few weeks later when, consulted by another young woman for the same trouble, whose history had been much the same of many repeated failures of various methods. In this case, also, the relief was immediate and complete, and the occasional use for two or three days of the remedy sufficed to render the patient practically free from the annoyance which through years had been in each heated season of very great degree. In each of these cases the withdrawal of the remedy was followed shortly by the reappearance of the urticuria. After each reappearance the phenomena entirely disappeared on the administration of the drug. No other influences were brought to bear or known to exist. The conditions, therefore, amount to control tests in two cases whose histories had been of failure in repeated trials of many measures.—J. P. Sawyer, M.D., in the *Cleveland Journal of Medicine*.

Deligation Results Found Two Years After a Major Operation Upon the Neck.—Dr. Thomas reports the necropsy in the case of a man 65 years old who, two and one-quarter years previously, had cut the internal, external and anterior jugular veins, as well as the common carotid artery, in an attempt at suicide. At the time, hemorrhage was controlled by clamping and ligation; secondary hemorrhage occurring, it became necessary to ligate the internal and external carotids. The patient recovered and resumed his occupation as a house painter. This he followed for nearly two years, when he came under observation again on account of severe cough and pain in the right chest. The temperature was high and expectoration copious. Rapid failure took place and death ensued. Upon postmortem examination, the blood vessels forming the circle of Willis appeared normal. The last half inch of the internal carotid artery was hollow, while the portion in the cavernous groove was represented by a fibrous cord. Upon the left side, the sterno-mastoid muscle was entirely replaced by cicatricial tissue. The common carotid was small and terminated abruptly five inches from the arch of the aorta in a mass of scar tissue, there mingling with the cut ends of the pneumogastric, sympathetic and some cervical nerves. Above this fusion, nothing but the two nerves, vagus and sympathetic, and a small artery could be found. This artery, not so large as a normal facial, came down from above and gave off the small facial, lingual and superior thyroid, and was the sole representative of the external carotid. No trace of the internal carotid or of the internal jugular as far as the base of the skull could be found. The inferior thyroid artery was smaller on this side, but the left vertebral was half as large again as its fellow. This, in fact, appeared to be the only special provision made for collateral circulation. The deep cervical artery was much smaller on this side. The left lung was normal, and therefore had not suffered from interference with the pneumogastric and sympathetic nerve. Upon the right side the common carotid artery seemed slightly larger than normal, but the superior thyroid, the lingual, the facial and the inferior thyroid were apparently not enlarged. In the right lung pathologic changes, with a collection of pus, had caused death. The conditions present illustrate how little reliance can be placed upon the theoretic collateral circulation laid down in the text-books, based on ordinary anatomic anastomosis, for with the exception of the enlarged left vertebral artery and some little enlargement of the right common carotid, all the other arteries were not only no larger, but were actually smaller; even the deep cervical artery was considerably smaller than its fellow of the opposite side.—*British Medical Journal.*

No. 61 Market Street (Occidental Buildings), Chicago, Illinois.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, 100 Washington St., Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the *Editor*, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street (Occidental Buildings), Chicago.

Original communications are only received with the understanding that they are exclusively contributed to this JOURNAL.

SATURDAY, NOVEMBER 6, 1897.

THE DEPARTMENT OF PUBLIC HEALTH.

It is with pleasure that we inform the members of the ASSOCIATION that the ASSOCIATION Bill to establish a Department of Public Health, and define its duties, has been approved in its entirety by the American Public Health Association at its last meeting at Philadelphia, and that body will co-operate with the ASSOCIATION and endeavor to have it placed upon the statute books.

There is some misapprehension in regard to the Bill, as appears by comments in certain newspapers, which should be relieved. In the first place, the ASSOCIATION yielded to the inevitable, no longer insisting that the head of the new Department should be a member of the Cabinet, to which position it heretofore found there were insuperable objections; objections which would indeed prevent the passage of the Bill should it be presented. The committee, therefore, have wisely framed their Bill on the lines of the Department of Agriculture, and there is little question but that in time the objections which now seem so unsurmountable will fade before the pressure of public opinion. However, the present proposition establishes the foundation and paves the way, but whether the period of trial will be long or short is of comparatively little consequence to the establishment and equipment of the new Department itself, which can run just as well if its head does not have that full measure of civic honor that the friends of the Department would like to see him have. At present, so far as the public is concerned, it is the efficiency of the service, and the thoroughness with which the new service shall cover the sanitary field, that they look to.

Some misapprehension has been felt and indeed expressed in some of the daily papers, to the effect that this measure was simply a revival of the old National Board of Health; that it was the establishing of a National Quarantine with greater powers; and to such we must reply that these misapprehensions are not founded on fact. In the first place, this Bill for the first time provides for thorough correspondence or conference to secure the co-operation of State, municipal and local boards of health "in establishing and maintaining an efficient and accurate system of notification of the existence and progress of contagious and infectious diseases and of vital statistics in the United States." While the proposed Bill goes further than any existing law in regard to the investigation of the cause of disease and the best means of its prevention, it makes no new regulation regarding quarantine. It takes quarantine as it finds it and simply transfers from the Secretary of the Treasury, a purely financial and commercial officer, the duties and supervision of so much of the work of the Marine Hospital Service as is included in this law, and so far as the service itself is concerned—an organization which, we are informed, attempted vainly to stem the tide of public opinion at Philadelphia by opposing the adoption of the measure—we have to say that it will make no difference to the officers of the service, so far as their duties are concerned, except that the head of the service, instead of reporting to the Secretary of the Treasury, will report to the Commissioner of Public Health, that is to say, that he will in future, if this Bill establishing a Department of Public Health shall become a law, report to some one presumably competent to give him advice and instruction—a position sadly needed when we consider the mismanagement of the present epidemic. The existing Quarantine laws then are transferred bodily from the Treasury Department to the Department of Public Health, a transfer which every dictate of humanity and of good government seems to suggest. The Bill goes further than any existing law in its utilization of the machinery of the present departments of government, and the great skill and adroitness with which the committee of the ASSOCIATION have prepared it, leaves all the departments and bureaus of the government in the same departments where they are now found. It simply provides for the better utilization of the information at their disposal, and affords a place for its collation and dissemination. The Bill also codifies all existing laws. That it is perfect in all details, we suppose is not to be expected so long as human nature itself is not perfect, but it is as near perfection as possible without further trial to secure it. We shall not only sincerely hope that every member of the ASSOCIATION will use his utmost influence to secure the passage of this wise, salutary and beneficent law, but that he will immediately write to his Member of Congress, and his [illegible] ivi [illegible] n the facts in regard to it, pointing out that the Bill, as already stated, differs from the old National Board of Health Act, inasmuch as it provides for a representative for every State Board of Health in the Union; that it consolidates the existing United States statutes; that it maintains all good and effective laws now in force, including the National Quarantine Act, and the Interstate Quarantine Act, and that it provides for the utilization of all information in the hands of the various departments, and affords a proper and suitable place for dissemination and promulgation. The Bill unloads the overloaded Treasury Department from duties which, under the existing state of affairs, were only nominal, and places them where care and supervision can be exercised. As the Marine Hospital Service is not interfered with, except as to the officer to whom the chief of the bureau shall report, it is seen that the opposition to the measure is not only gratuitous and unnecessary, but unwise and unscientific. We, however, are of opinion that this alleged opposition is confined to a limited number of officers who are compelled to act under the instruction of the present chief, who is said to view any change of whatever character in the existing régime as a bad one. Write us for a copy of the bill.

THE PHYSIOLOGY OF THE THYROID GLAND.

The physiology of the thyroid gland is a subject that has been largely worked out within the past five or six years; that is, what we know of it with any degree of certainty. Theories had, of course, been offered and some of them have been confirmed; the brilliant therapeutic results following the physiologic investigations of Schiff, Horsley, Vassale and Gley and their practical application in myxedema are, as has already been stated in the Journal, one of the most important of recent medical acquisitions and the one, perhaps more than any other, that illustrates the close relationship between physiologic research and rational therapeutics. The still more recent isolation of thyroiodin, which seems to be at least the chief of the active principles of the gland, has thrown additional light upon the subject. The old notion that the gland acts as an apparatus for regulating the cerebral blood supply and which was held as a possible truth as late as the 1892 edition of "Landois and Stirling's Physiology," is almost forgotten and thrown aside with the revelations of the secretory functions, previously suggested by Rogowitsch and so fully demonstrated by Vassale, Gley, Baumann and others within the past few years.

It is possible, however, that like some other glandular organs, it may have other functions than that of supplying to the organism some useful secretion or of disposing of some deleterious substance, and that there may be some truth still in the older hypothesis. In June of the present year, Professor Cyon reported to the Paris Academy of Sciences that his experimental studies had led him to the opinion that all the chief phenomena of Graves's disease, the goiter, exophthalmus and the tachycardia, as well as the visceral disturbances, were explainable by the action on the heart and the thyroid of the sympathetic system influenced by the depressor nerve. In a still later communication to the same body (Sept. 12, 1897), he further reported that he had ascertained that the thyroiodin produced by the thyroid is a stimulant of the nerve centers that govern the heart and the circulation, and that the toxic substance removed from the blood by the gland is the iodin salts it contains, which have in their natural state a directly paralysant action on the depressor and pneumogastric nerves. It thus transforms a dangerous poison into a directly beneficial substance, the good effects of which he claims are not dependent upon the iodin contained.

The heart reciprocally acts upon the thyroid through the nerve filaments passing to the laryngeal nerves and thus controls the production of thyroiodin, which in turn is indispensable to its own normal function.

This secretory function, however, is not, according to Professor Cyon, the only one possessed by the thyroid gland. He revives the old and neglected regulator theory of the thyroid function, and holds that, situated as it is near to the point where the carotid enters the cranium, it may act as a safeguard to the circulation, forming "a kind of secondary circuit of feeble resistance," and that this action is also presided over by the heart. This causing dilatation of the gland acts in two ways, 1, by opening the flood gates, so to speak, in cases of sudden danger; 2, by increasing the secretion of thyroiodin in case of permanent danger, and in either case the action is beneficial. The briefly reported communication does not give many details that might be desirable, but the above is its substance, and it certainly affords suggestions that can come into play in considering some of the facts already ascertained in regard to the functions and properties of the organ. The bearing of these ideas on the treatment of Graves's disease is pointed out by Cyon, especially as regards the indications for the use of thyroiodin and the very recently recommended section of the sympathetics. In cases of the vascular or ordinary hyperemic type of the disease the use of thyroiodin is counterindicated, and Cyon recommends the internal administration of iodin, and in cases of imminent danger the section of the depressor nerves may be tried. The relation of the heart's condition to the varying thyroiodin contents of the gland is also suggested by these views, as a possible subject worthy of investigation and other questions bearing upon the commonly received and recent views of the physiology or functions of the thyroid gland will readily occur to the reader. If, for example, its function is to transform and neutralize iodin as a toxic agent in the blood, how will this fact bear upon that other view recently advanced and claimed to be supported by good evidence, that its goitrous hypertrophy is associated with a deficiency of that substance. Professor CYON's views are certainly suggestive of some modification of recent physiologic theories and his communication ought to be an incitant of further studies on some of these points.

He does not confine the regulatory action in the circulation to the thyroid alone, but suggests as possible that the thymus, situated near the entrance of the vertebrals into the cranium, the accessory glands situated near vital organs firmly enclosed in sheaths like the kidneys and testicles, and the pituitary body may also have this office to some extent as well as that of furnishing an internal secretion. In the course of time the substance of his investigations should appear in a more elaborated form and we can better estimate the validity of his conclusions.

FAITH-CURE AND HYSTERIA IN THE NINETEENTH CENTURY.

A recent discussion, before the Chicago Physicians' Club, of faith-cure, by several clergymen, led to assertions monotonously familiar to students of the fetichic side of medicine. The Club likes to amuse itself, and sometimes at its own expense. One of the gentlemen present reported two miracles at Lourdes. The gentleman conscientiously believed himself free from a bias to which his training as an ecclesiastic however strongly predisposed him. Moreover, his surroundings at Lourdes further biased him in the belief that miracles could be there performed. He was therefore in no judicial frame of mind when he saw in the midst of an enthusiastic crowd of fanatics, a " woman with a cancer extending from the lip to the breast cured in an instant." The case, as seen during the enthusiasm of a crowd, with no opportunity for calm investigation, could have been a pure suggestion. Its occurrence has been repeatedly denied by other more judicial investigators. ZOLA (preface to "Lourdes") thus sums up the evidence as to a precisely similar case which took the place of the first after its novelty had worn off.

"I interviewed a number of people at Lourdes and could not find one who would declare that he had witnessed a miracle. All the cases which I describe in my book are real cases in which I have only changed the names of the persons concerned. In none of these instances was I able to discover any real proof for or against the miraculous nature of the cure. Thus in the case of Clementine Trouve (who figures in my story as Sophie) the patient, who, after suffering for a long time from a horrid open sore on her foot, was suddenly cured, according to current report, by bathing her foot in the piscina, where the bandages fell off and her foot was entirely restored to a healthy condition. I investigated the case thoroughly. I was told that there were three or four ladies living in Lourdes who could guarantee the facts as stated by little Clementine. I looked up those ladies. The first said no, she could not vouch for anything. She had seen nothing. I had better consult somebody else. The next answered the same way, and nowhere was I able to find any corroboration of the girl's story. Yet the little girl did not look like a liar and I believed that she was fully convinced of the miraculous nature of her cure. It is the 'facts,' which of themselves lie. Lourdes, the grotto, the cures, the miracle, are indeed the creation of the need of the occult, that necessity for credulity which is a characteristic of human nature."

The case which came under the gentleman's own observation, and for which his evidence must be accepted, was one of hysteria from utero-ovarian disorders. Certain surgeons and physicians assumed that the hysteric symptoms were due to the utero-ovarian condition and proposed operation. This was not consented to, and the patient went to Lourdes, where she recovered from her hysteric symptoms, albeit the utero-ovarian state remained unchanged. This case recalls the very similar "miracle" of JOHN ELIOT, the Apostle to the Indians, of which Dr. OLIVER WENDELL HOLMES gave the following characteristic explanation:

"I do not want to say anything against MARY CHASE, but I suppose that getting nervous and tired and hysteric she got into bed, which she found rather agreeable after too much housework and perhaps too much going to meeting, liked it better, curled herself up into a bunch which made her look as if her back was really distorted, found she was cosseted and posseted and prayed over and made much of, and so lay quiet until false paralysis caught hold of her legs and held her there. If some one had hollered fire it is not unlikely that she would have jumped out of bed as many other paralytics have done under such circumstances. She probably could have moved enough if any one could have made her believe that she had the power of doing it. *Possumus quia posse videmur.* She had played possum so long that at last it became non-possum."

The epidemic of faith-cure just now prevailing takes its root in the old fetich practices of Shaman priests when medicine and theology were one. Great as have been the claims for Lourdes they do not exceed those made for that self-deluded faith-curer, VALENTINE GREATRAKES. He was a man of considerable culture for the seventeenth century. An officer in CROMWELL's army, a pious puritan, he never molested other religionists over whom he was placed in Ireland. After the Restoration, VALENTINE GREATRAKES, according to JEAFFERSON, lost his office and was reduced ("Stories About Doctors") to a private gentleman. On his small estate he labored on with good results, introducing into his neighborhood a more scientific system of agriculture giving an unprecedented amount of employment to the poor. He missed the excitement of public business, and his energies deprived of the vent they had for years enjoyed made him the victim of his imagination, which acting on a mind educa [illegible] sel [illegible] f fanatic introspection led to a series [illegible] usions.

He first had attacks of pensiveness and dejection; ere long he had a "strange persuasion" in his own mind, of which he was not able to give rational account, that he could cure the "king's evil." Patients afflicted therewith were in due course brought before him and on his touch they recovered. When the royal touch was believed in as a cure for scrofula the distinction between strumous and other swellings was by no means clear even to physicians of repute. Many who underwent the manipulation of "annointed rulers" suffered only from swellings, from which as a matter of course nature would in a few weeks have relieved them. Many of VALENTINE'S patients were evidently suffering not under scrofulous affections but comparatively innocent tumors. A second impulse gave him the power of curing ague. A third inspiration, or "celestial aura," imparted to him the command, under certain conditions, over all human disease. His methods of operation were various. When an afflicted person was laid before him he usually offered up a prayer to God to make him the humble instrument of divine mercy. Invariably, when a patient derived benefit from his treatment he exhorted the patient to offer up thanks to God. After the initiatory supplication the operator passed his hands over the affected part of the sick person, sometimes over the skin itself and sometimes over the clothes. The manipulations varied from delicate tickling to violent rubbing, according to the nature of the demon by which the diseased people were tormented. GREATRAKE'S theory of disease was the scriptural one. The morbific power was a devil, which had to be expelled from the frame in which it had taken shelter. Sometimes the demon was exorcised by a few gentle passes; occasionally it fled at the verbal command of the physician, or retreated on being gazed at through the eyes of the mortal it tormented, but frequently the victory was not gained till the healer rubbed himself into a copious perspiration. Dr. HENRY STUBBE, a famous physician in Stratford-upon-Avon ("Miraculous Conformist," 1666), gives the following testimony to GREATRAKES:

> "Proofs that he revives the ferment of the blood.—Mr. BROMLEY'S brother of the Upton-upon Severne, after a long quartane ague had by a metastasis of the disease such a chillness in the habit of the body that no clothes could possibly warm him; he wore upon his head many spiced caps and tenne pounds weight of linnen on his head. Mr. GREATRAKES stripped him and rubbed him all over, so that the bath never heated him up as did the hand of Mr. GREATRAKES; this was his own expression. But Mr. GREATRAKES, causing him to cast off all that multitude of caps and cloths, it was supposed that it frustrated the happy effect, for he felt the recourse of his disease in some parts, which rendered the cure suspicious. But as often as Mr. GREATRAKES came and rubbed him he would be all in a flame againe for half an hour. The experiment whereof was frequently practiced for five or six days at Ragly."

GREATRAKES himself speaks of his more violent curative exertions making him very hot. But only occasionally had he to labor so vehemently. His eye (the glance of which had a fascinating effect on people of a nervous organization) and his fantastic ticklings usually sufficed to produce the results required.

The fame of the healer spread far and wide. Not only from the most secluded parts of Ireland, but from England, the lame and blind, the deaf, dumb and diseased made pilgrimages to the Squire of Affane. His stable, barn and malthouse were crowded with wretches imploring his aid. The demands upon his time were so many and so great that he set apart three days in the week for the reception of patients and on those days from six in the morning till six in the evening he ministered to his wretched clients. He took no fee.

He did not profess to be able to cure everyone. An adverse influence such as the sins of a patient or his want of faith sufficed to counteract the healing power. GREATRAKES could affect only those who were susceptible. The people of Warwickshire crowded by thousands to him and he touched, prayed over and blessed them and sent them away rejoicing. From Rugby he went to Worcester, at the request of the lord mayor and aldermen of Worcester, and from Worcester he was carried up to London. Lord ARLINGTON commanded him "to appear at Whitehall and tumble in his particular fashion" for the amusement of CHARLES II. A man who could cure gout by a touch would have been an acquisition to the court which then ruined English manners. Fashion and wary opulence laid their offerings at his feet. For a time he ruled from Soho to Wapping. Justice GODFREY gave him rooms for the reception of patients in his mansion in Lincoln's Inn Fields, and thither flocked the mob of the indigent and the mob of the wealthy to pay him homage. Mr. BOYLE (the brother of the Earl of Orrery), Sir WILLIAM SMITH, Dr. DENTON, Dr. FAIRCLOUGH, Dr. FABER, Sir NATHANIEL HOBART, Sir JOHN GODOLPHIN, Dr. WILKINS, Dr. WHICHCOT and Dr. CUDWORTH were among his most vehement supporters of the sterner sex. But the majority of his admirers were women. VALENTINE GREATRAKES, as the lion of the season, performed with wondrous results on the prettiest or most hysteric of the ladies present. His intimate friends held that the curative property that came from him was a subtle aura effulgent and of an exquisitely sweet smell that could only be termed the divine breath. According to Dr. HENRY STUBBE:

> God had bestowed upon Mr. GREATRAKES a peculiar temperament or composed his body of some particular ferments, the effluvia whereof being introduced, sometimes by a light, sometimes by a violent friction, should restore the temperament of the debilitated parts, reinvigorate the blood and dissipate all heterogenous ferments out of the bodies of the diseased by the eyes, nose, mouth, hands and feet. I place the

gift of healing in the temperament or composure of his body because I see it is necessary that he touch them. Besides, the Right Honorable Lord CONWAY observed one morning, as he came into his lordship's presence, a smell strangely pleasant as if it had been of sundry flowers, and demanded of his man what sweet water he had brought into his room he answered none, whereupon his lordship smelled upon the hand of Mr. GREATRAKES and found the fragrancy to issue thence, and examining his bosom he found the like scent there also. Dean RUST gave similar testimony, and "Sir AMOS MEREDITH, who had been Mr. GREATRAKES' bedfellow, did the like,"

VALENTINE GREATRAKES' triumph was, however, of short duration. His professors were made the butt of ridicule, to which his presence of mind and volubility was unable to respond with effect. His enemies asserted that his system was only a cloak under which he offended the delicacy of virtuous women and roused the passions of the unchaste. His conversation was represented as compounded of the blasphemy of the religious lunatic and the blasphemy of the obscene profligate. His boast that he never received for his remedial services was met by a flat contradiction to the effect that he received £500 at a time from one individual. The last accusation was never absolutely disproved. The tide of slander was too strong for him. He retired to his native country. Of his sincerity at the outset of his career as a "healer" there can be little doubt. In many respects GREATRAKES resembled the paranoiac "SCHLATTER the Healer," who died a victim to a self-imposed journey during a forty-day fast and was later personated in Chicago by "Rattlesnake Dick," whom Dr. RAUCH more than once drove from Illinois.

What is to be regretted in the Chicago Physicians, Club discussion is that men without medical education and judicial training as to the value of evidence were permitted to speak with authority on a subject as to whose merits experience has demonstrated evidence like theirs to be totally valueless. The invitation, even though rescinded, to a "healer" (notoriously driven from Omaha on excellent legal grounds, by the health authorities) was especially to be regretted. Every newspaper in Chicago exploited this invitation in a way that can not fail to add to this man's dupes.

THE EVILS OF TEA-DRINKING.

In these days of Tea-worship it is well to call attention occasionally to the deleterious effects of the excessive use of this beverage. In their ardent advocacy of the "cup that cheers but not inebriates," the apostles of temperance are too prone to forget that there are other intemperances than alcoholic ones, and of these none is more vicious than the pet vice of refined and polite society, tea-debauchery.

In former years the tea-drinkers were usually to be found among nervous old persons. The association of the fidgety old maid and her cup of tea is proverbial. In the present day the temptation of tea-tippling is persistently offered to us from childhood, and nearly every one is more or less addicted to its use. The fashionable afternoon tea has done much to extend and perpetuate the vice. Otherwise sensible and temperate men and women will actually indulge in tea-debauchery to the extent of as much as a dozen cups during the social duties of a single afternoon. Such excess is not generally the result of wilfulness or pernicious desire, but is due to the innocence of the baneful results of the practice, and is thus capable of correction by a campaign of education.

The manner in which the tea-habit has increased is alarming; it is fast becoming universal. It almost seems that soon only those already addicted to some other form of intemperance will form the abstemious class. Tea is drunk at all hours, with food and without, and is taken hot and cold. There is some excuse for the popularity of the hot infusion. In common with other hot beverages it is very acceptable as a stomachic and general stimulant, but it is the heat and not the infusion that stimulates. A cup of hot bouillon will always prove as agreeable and more nourishing and stimulating. No excuse can be found for the senseless habit of drinking the usually harmful iced tea. It is simply an expression of the natural perversity of human nature when given up to a pernicious habit; unsatisfied with the excess in its ordinary form, some new means, without reason or advantage, are devised for its more elaborate practice. In warm weather many other cold beverages are better. Unless excessively sweetened, lemonade, orangeade, etc., are vastly more palatable and certainly harmless. Another folly of the tea-drinker is dilution of the infusion with milk, and further perversion with sugar. The ill effects of tea-drinking are sufficiently plenteous without the addition of the large amount of sugar taken daily, cup by cup, by a tea devotee, in itself quite sufficient to cause obstinate gastric derangements and their manifold complications.

Tea leaves contain from 2 to 4 per cent. of an active principle variously called thein, caffein and guaranin, a volatile oil giving odor and flavor, and tannin or tannic acid in the proportion of about 15 per cent. The alkaloid is found in combination with the tannic acid. Fortunately, since the establishment of rigid tea inspection, metallic adulterants, such as lead, formerly used to color black tea, need not be considered. Ordinary tea-drinkers simply infuse the leaves with hot water for a short time and in this manner the alkaloid and the aromatic elements are extracted without any undue proportion of tannin. In many households, however, tea is allowed to stand in the pot, either on the table or on the stove, or is actually boiled; in such a case a large proportion of the harmful tannin is taken up by the infusion. The least injurious beverage is that prepared by infusing the leaves with boiling water for a very short time and immediately pouring the prepared infusion away from the leaves and sediment.

The deleterious effects of tea are in some degree due to the alkaloids, which when taken in constant or excessive doses produce insomnia, restlessness, mental depression and general nervous derangement. Occasional small doses act as cerebral stimulants; poisonous doses may produce great prostration and death. However, the greatest injury of tea-drinking is due to the astringent action of the tannin ingested; what may be called a tanning of the sensitive mucous membrane and its contained glands along the whole gastrointestinal tract is gradually effected. This leads to a loss of sensibility to food stimuli, imperfect secretion of the digestive elements and insufficiency of intestinal movements, resulting at first in flatulence and chronic constipation and ultimately in obstinate indigestion and its associate and consequent evils. It is true that occasionally a cup of hot tea does stimulate digestion, but it is the heat that stimulates and not the alkaloid.

Excessive coffee-drinking is also an obnoxious habit, although in a less degree than tea-drinking. Dyspepsia, insomnia, cardiac derangements and other ills are laid at its door. On account of the identity of their alkaloids there has been a general disposition to consider tea and coffee the same in their physiologic effect. This idea is erroneous, as the alkaloids are not the only constituents of these substances. Exclusive of its alkaloids, coffee contains aromatic and other agents which render it a stimulant to the whole digestive tract—sialogogic, stomachic, carminative, deodorant, and mildly laxative. Tea has no such auxiliary effect on the digestion, and in constant and excessive quantities impedes and destroys it. In addition coffee has been proven to be a more prompt and efficacious nerve restorant.

While protesting against the pernicious use of either substance as a daily beverage, from a medical standpoint, our preference is emphatically for coffee. Contrast the vigorous, refreshing odor and flavor of a good cup of coffee with the delicate fragrance and insipid taste of even a high grade tea; contrast the clear complexion and general physical aspect of the individual whose morning meal is a bowl of diluted coffee and who takes his after-dinner cup, with the nervous, emaciated, habitually constipated dyspeptic whose "eye opener" and "night cap" is tea, and all reason for argument as to our preference ends.

CORRESPONDENCE.

Medical Law in Wisconsin.

Milwaukee, Oct. 26, 1897.

To the Editor:—In the article on "National Medical Legislation," by Dr. Greeley, in the Journal, October 23, the Secretary of the Wisconsin State Society is quoted to the effect that we have no efficient medical law in the State. That was undoubtedly true when Dr. Greeley got his information, but it is not true now. We have a law which has been in operation several months and is working well. The law established a State Board of Medical Examiners. A diploma from a recognized medical school or satisfactory examination before the Board is required.

My impression is that Dr. Greeley's article is incorrect as regards Indiana. I am quite sure that this State also has recently enacted a very efficient law.

Very truly yours, Gilbert E. Seaman, M.D.

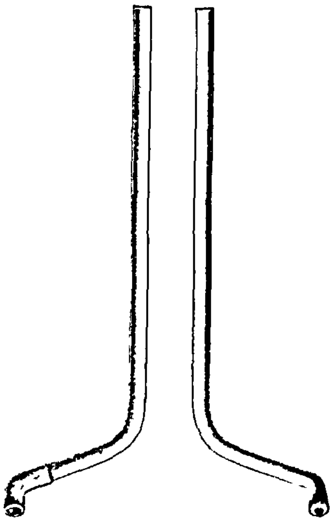
NEW INSTRUMENTS.

ORAL RIGHT AND LEFT EUSTACHIAN CATHETERS AND TENT HOLDERS.

BY EPHRAIM CUTTER, M.D.
NEW YORK.

Experiment has shown that the Eustachian tubes have three angles each of 45 degrees, viz.: 1. Upward from the horizontal pharyngeal plane. 2. Outward right and left from a vertical antero posterior medium pharyngeal plane. 3. Backward from a medium transverse pharyngeal plane.

It is evident that if these angular measurements are correct for the average Eustachian tubes, the catheters for them must conform to these angles. Again, the access through the mouth behind the soft palate is freer and easier than through the narrow nares with sensitive cavernous erectile tissues on the turbinated bones and with a vomer, all which often are irregularly formed, placed and twisted, hindering facile movements to the catheters, Eustachian.



1. Oral catheter for left Eustachian tube. 2. Oral tent holder for right Eustachian tube.

Again, if the aurists are rhinologists, the mirror will allow "them" (him or her) to see the catheter enter or entered into the Eustachian tube, so that its penetration is proved by sight. With these contrivances it is hoped that operators will find access to the Eustachian opening better than with the conventional catheter which does indeed turn upward and outward but not backward.

Prof. J. Solis Cohen, of Philadelphia, recommends that patients have their own oral catheters. The material is silver or German silver.

Of course these angles will not suit all cases, as it has been found that the Eustachian orifices vary. But when the catheters are introduced *per os* it is easy to adjust them to these variations, which adjustment is impossible when the catheter enters through the nares.

Some years ago the writer made oral Eustachian catheters somewhat on these angles but they were defective because they did not have in addition the upward 45 degree angle which the present models submitted possess.

A New Transportable Medical Illuminator is described in the *Jour. Méd. de Paris*, which is merely a piece of platinum "moss" set in the center of a reflector and attached to the ordinary Paquelin thermocautery in the place of the knife. The illumination produced is said to equal that of quite a strong electric light. The thermocautery apparatus can be substituted by a still simpler contrivance, a tube containing a sponge moistened with kerosene, connected with a Richardson bulb and cock.

Pendulum Apparatus for Stiff Fingers and Wrists.—It has been six years since Krukenberg first suggested applying the principle of the pendulum to an apparatus to correct stiff articulations. Nebel has now perfected a small instrument for the purpose which accomplishes the desired result with astonishing rapidity and ease. It is attached to a small board clamped to the edge of a table, on which the hand rests, with the pendulum swinging freely below. It can be adjusted to any size and to any part of the hand or wrist. It is described in full with four cuts in the *Ztschrft. f. Orthop. Chir.*, Vol. v, No. 1. Nebel states that patients who used to resist and scream at all his manual attempts to mobilize their joints, now accomplish it alone, with this simple little apparatus, in an incredibly short time.

The Wire Saw in Trephining.—The JOURNAL quoted an article in the issue of September 5, on the advantages of Gigli's wire saw, which stated that for all bone sections except those of the skull, it seems to be an ideal instrument. The next foreign mail brought an article in the *Cbl. f. Chir.* of August 14, by Prof. A. Obalinsky on the technique of trephining based on a wide experience, and the instruments recommended are Collin's crown perforator and Gigli's wire saw. A tongue-shaped flap is cut in the soft parts and raised. Five to seven holes are then made with the perforator, through the entire thickness of the skull down to the hard membrane, two at the base of the flap and one at the tip, with the rest regularly arranged along the sides. The membrane is detached from the skull with a fine elevator and the wire saw introduced at one hole and passed through and out at the next, held in a Deschamps needle, a curved canula or an ear sound. There is no jar, no traumatism, and the bone is cut clean and exactly where required close to the root of the broad flap, which rapidly heals into the tissues when replaced.

PUBLIC HEALTH.

Bicycle Accidents 10 per cent.—Out of 4,000 claims reported by the Ætna Life, 981 were due to falls, 481 carriage and wagon accidents, 413 bicycle accidents, 264 cuts, 194 falling of heavy articles.

Health Association Names Officers.—The American Public Health Protective Association elected the following officers: President, Charles A. Linsley of New Haven; vice-presidents, Benjamin Lee, Philadelphia, and John C. Schrader, Iowa City, Iowa; secretary, Henry C. Probst, Columbus, Ohio; treasurer, Henry C. Holton, Brattleboro, Vt. Ottawa was chosen for the convention of 1898, and Knoxville has put in a claim for 1899.

Instruction in State Medicine.—Hamline University of Minneapolis, Minn., as per catalogue for 1896-7, has established a chair of preventive and legal medicine and medical insurance. C. A. McCollom, M.D., head physician Modern Woodmen of America, is the lecturer. The medical branch of the above university is known as the College of Medicine (Minneapolis College of Physicians and Surgeons). We congratulate the institution on this advanced movement.

On Noise Nuisances Dangerous and Detrimental to Health.—Several letters have lately appeared in the daily newspapers, one of which made remarks as follows: The nerves of the ear are the most sensitive of the whole body, except those of the eye. Every harsh sound which strikes the ear throws the particles of the brain into commotion. This incessant vibration caused by the incessant discords of a city like New York does much to impair health. It may not be noticed by many who have grown used to it, or as Josh Billings would have said "become manured to it," but whether they notice it or not their brain matter is vibrating in unison with every harsh noise that strikes their ears. In many diseases, especially the diseases incident to brain work, discordant noises are not merely disagreeable. They are deadly. The Board of Health knows this. It also knows that a very large part of the population of New York is doing indoor work and is liable to the nervous troubles incident to it.—*Public Health Journal.*

On the Milk Supply of Cities.—Among the papers read before the National Conference of Mayors and Councilmen, held at Columbus, Ohio, during the last week of September, was one on "The Influence of a Pure Milk Supply on the Death Rate of Children," by Nathan Strauss, of New York, the founder of the depots for the supply of sterilized milk to the poor. In the course of it, he said: "There is practically no milk delivered for general consumption in cities that is fit to be fed in its natural state to young children." After having given a large number of mortality statistics and outlined the work done by him in establishing pure-milk stations in the City of New York, he went on to say: "I think I have fairly demonstrated the proposition that many thousands of infant lives are annually sacrificed by the neglect to supply, for the nutriment of children, milk which has been sterilized. I hold that neglect to be criminal, and I leave it to you to fix the responsibility for it. We punish murder with the penalty of death, and yet we allow murder to be committed by the wholesale in every populous community of this land, with no thought of its punishment and little thought of its prevention."

Violent Deaths in Great Britain in 1896.—Some interesting statistics have recently been printed in London relative to deaths by accident in Great Britain. From these figures it appears that while 824 deaths were attributed to railroads in one year, there were no less than 1,054 people killed by vehicles other than railway. Of these, 236 deaths were caused by vans and wagons and 372 by carts. Besides these, 273 deaths are put down as being attributed to horses. The destructiveness of water appears in the item of 2,172 deaths caused by drowning. Lightning killed 15 people and sunstroke 41, while 91 died from exposure to cold. No less than 348 of the male sex were sent to their final account by falling down stairs, and 50 met their doom by tumbling out of open windows. Sixteen people died from football, while the game of cricket is responsible for the demise of three. Two deaths are ascribed to tight boots and one to barbed wire. In the cases of burns, scalds and explosions, English women are more unfortunate than the men. From this source 1,186 females met their death, as against 1,005 men; but when it comes to suicide the men have the call, as 2,052 males shuffled off the mortal coil by their own hands, while only 677 women committed self-destruction.—*Indemnity.*

Sanitation of Dairies.—To make good butter one must have good milk, and this comes only from healthy cows, fed on good sweet pasture or on good sweet grain and other forage, and which have pure water to drink and pure air to breathe. Certain obnoxious weeds, leeks, wild onions, ragweed and others, give the milk and the butter made from it a decidedly bad flavor; so also does damaged, rotten silage, moldy corn fodder or hay, and musty, damaged grain. Impure water has its effect, both on the health of the animals and the quality of the milk. In many pastures are some small [illegible] in which the cows stand during the heat of the day to rid themselves of flies. The water in these becomes filthy and is kept stirred up by the movements of the cattle, and where, as is often the case, it is the only water obtainable, the cows are compelled to drink it. This can usually be avoided by fencing the pond and keeping the cattle out. If this water is needed for the cattle it can be drawn out in a pipe laid on the lower side in trough from which the cows can drink. In a close, crowded and ill-ventilated stable, where there is too little air space for each animal, the air becomes foul from the exhalations, and this affects the milk as well as the health of the animals. The remedy in this case is to provide more room for the stock and better ventilation. The stable should be kept as clean as possible and the cows well bedded and clean. The utmost cleanliness should be observed in milking. All dirt should be brushed from the cow before beginning to milk, and it is best to dampen the udder and flank of the cow to as to prevent the dust and fine dirt from falling into the milk. The milk should be strained immediately after milking and not allowed to stand in the cow stable any longer than absolutely necessary.—*Bulletin United States Department of Agriculture.*

The Opinion of the Quarantine Officer of the Louisiana Board of Health.—Dr. C. P. Wilkinson, formerly President of the Louisiana Board of Health, and at present Resident Physician at the Mississippi Quarantine Station, writes the *Times-Democrat* as follows. His opinion is not only valuable, as being the deliberate judgment of an officer of many years' experience, but from a historic standpoint:

HOW THE FEVER GOT IN.

[From the New Orleans Times-Democrat, Oct. 25, 1897.]

Mississippi River Quarantine Station,
Oct. 23, 1897.

To the Editor of the Times-Democrat.

In the summer of 1874 yellow fever broke out at Fort Barrancas, Fla., on the west shore of the entrance to Pensacola Bay. The disease rapidly spread in the garrison. Dr. Sternberg, post surgeon of the fort and now Surgeon General of the Army, having a very severe attack. Rigid investigation into the source of the disease failed to locate its origin. Some time after the subsidence of the epidemic at that post it was learned that a bark sailed into the entrance to the bay one summer evening and at dusk cast anchor at no great distance from the fort. After dark two soldiers from the garrison clandestinely visited this bark, making some purchases, remaining on board some hours. At daylight in the morning the bark sailed on to the quarantine station, further up the bay. This bark was from Havana, and had on board at the time several of the crew ill with yellow fever. The two soldiers who had gone on board were the first taken ill with yellow fever at the fort.

In 1886 yellow fever appeared at Biloxi, Miss. The origin of the case was undeniably traced to communication with infected vessels at the Ship Island Quarantine Station. These two incidents are cited to show how easily contagious diseases may be carried from infected premises, and also to show that notwithstanding the discipline of the army and of the national quarantine service how easily either or both may be evaded.

In 1887 the citizens of Biloxi and of other points on the Mississippi Sound urged upon their Congressmen the request that the Ship Island Quarantine Station should be removed to some other more remote locality. The reasons that this removal should be caused were patent to all, the principal one being the impossibility of preserving isolation of vessels in quarantine at that place. To one familiar with the Sound coast this argument was insuperable. The Mississippi Congressmen in their efforts to secure the passage of the act of Congress necessary were wisely and ably seconded by the then Surgeon General of the Marine-Hospital Service, Dr. John B. Hamilton, who readily saw the necessity of such removal. Congress passed the act in 1888. Surgeon General Hamilton appointed a commission to select a better site for the station. He appointed Surgeon W. H. Hutton, after whom the mechanics' detention camp at Avondale is now named. Assistant Surgeon H. R. Carter, now in New Orleans, both of the Marine-Hospital Service; Capt. Parker of the coast revenue cutter; and, to show his deference to the people and the interests of the vicinity, invited the people of Biloxi to name the fourth, and the Louisiana Board of Health to name the fifth member of the commission. Dr. Maybin was named by Bilox and I was named by our Board of Health. After carefu examination of the various possible locations for a quarantin station the northern end of Chandeleur Islands was unani mously selected by this commission as being admirably adapte to the purpose. The location was accepted. A quarantin plant was there erected.

Ship Island Quarantine Station was abandoned, and th buildings being considered infected, were burned. In 1893 terrible storm swept across lower Louisiana and Mississippi The Louisiana Quarantine Station, erected at about the sam time as the Chandeleur Island station, because of superior con struction, passed through the hurricane without loss of lif and with little damage to property, and was at work disinfect ing vessels the next day; whereas the Chandeleur Island Sta tion, because of inferior construction, for which the nationa government is responsible, was demolished, and the next da nurses, patients and stewards were floating about the Gulf o Mexico, drowned and killed in the wreck.

The following year the Marine-Hospital Service moved th quarantine station back to Ship Island, in spite of the wishe and in defiance of the protests of the inhabitants of the Soun coast, and with amazing and fatal disregard of the elementar principle necessary for a properly located quarantine station *i. e.*, the possibility of isolation.

From Ship Island Quarantine Station has come to th Southern country this visitation of yellow fever. Dr. Guitera states that this visitation, like all our visitations, has com from Cuba. It is a matter of record that the widespread ep demic of 1847 was brought from Vera Cruz by our returnin soldiers from the Mexican war. The fever of 1867 was brough from Mexico to Indianola and thence to New Orleans.

The following showing the arrival of vessels at Ship Islan Quarantine Station from June 11 to August 4 of this year wil furnish much food for reflection. I have excluded the arrival *previous to* and *subsequent to* the *first* and *latter, respectively* of the above dates, and I have also excluded all arrivals excep those from badly infected ports:

ARRIVALS AT SHIP ISLAND QUARANTINE FROM CUBAN PORTS.

June 11.—Schooner Oscar G., from Havana.

June 12.—Brig Estella, from Havana; one case yellow feve in quarantine.

June 12.—Schooner Eleanor, from Havana; five cases inter mittent fever in quarantine.

June 14.—Schooner Iolanthe, from Cienfuegos.

July 7.—Schooner H. J. Powell, from Havana.

July 11.—Schooner Florence and Lillian, from Sagua.

July 14.—Schooner James Slater, from Sagua.

July 19.—Schooner Pickup, from Cardenas.

July 20.—Schooner Charles Fowler, from Calbarien.

August 4.—Schooner Eleanor, from Havana.

The sanitary inspector, United States Marine-Hospital Service, stationed at Havana, writes under date of June 19, 1897, to the Surgeon General:

"American schooners laden with lumber from the ports in the South still continue to come to this port and they invariably go to Talapiedra wharf, where they remain seven to ten days. There are two such vessels at that wharf at present writing."

All summer long the above is repeated from Havana nearly every week to the Surgeon General. Talapiedra wharf has long been considered the most dangerously infected place in all Havana. All the officers of the quarantine service on the lower Mississippi are very keenly alive to this fact, and pay very particular attention to vessels from that locality. All practical quarantine officers know very well that vessels from that wharf are always very dangerously infected, and that isolation and disinfection must be extreme to treat them successfully. Now, where do these American schooners, laden with lumber, going to Havana, sail from? Ocean Springs, Scranton, Ship Island, the Mississippi Sound coast! Who are they manned and officered by? Residents of the Sound coast! That the men on board these vessels and their friends from the shore hold liberal communication both before and after disinfection is a foregone conclusion to everyone who knows the number of boatmen, fishermen and pilots along the Sound coast, and also knows of the quantity of smuggled goods, and of the rumors of organizations of smugglers who sail in and about the shipping in Ship Island harbor. Isolation is essential to the success of any quarantine station. Isolation can not be and has not been maintained at Ship Island quarantine.

Another port very highly infected, Colon, has sent infected schooners to Ship Island Quarantine Station. Arrivals at Ship Island Quarantine from Colon:

July 13.—Schooner Aloha, two cases malarial fever; in quarantine.

July 25.—Lena R. Storer, two cases malarial fever; in quarantine.

August 7.—Schooner Palos, three cases malarial fever; in quarantine.

It will be observed that everyone of these schooners had two cases of fever on board while in quarantine. If the doctor at Ship Island made a mistake in diagnosis, the disease may have been yellow fever, and the germs may have reached the coast from the Palos, the Storer and the Aloha.

The yellow fever prevailing at Colon this summer is of a very highly contagious nature. It came originally from Guayaquil to Panama, infected nearly every vessel trading at Panama; crossed to Colon and spread from there to Bocas del Toro, Port Limon, to Kingston, Jamaica, to Ship Island and to the Southern States. Early in the summer, vessels at Colon began losing passengers and men from yellow fever. Cases were dropped from vessels sailing away from Colon at Barbadoes, at Tortugas, at New York. Vessels coming here reported the loss of passengers at sea who had been on shore at Colon, with symptoms which left no possible doubt in my mind they had died of yellow fever. How many other cases occurred of which I know nothing I can not say; they are probably numerous.

From every quarantine station reporting sickness on vessels from Colon, all save one reported yellow fever. The sole exception was the Ship Island Quarantine Station. Three vessels at that station from Colon, a highly infected place, with seven cases of fever on board! Three of those lumber-laden schooners laying seven and ten days in port and everybody on shore! It is almost certain that these seven were yellow fever. I say this with no uncharitable feeling for my brother physician in charge of that station; but the logic of facts points almost inevitably to that conclusion. Ask any practical seaman, any observer of human nature, if the friends and relatives of crews of vessels in quarantine, only ten miles away, will seek an interchange of visits! Visits to home, to loved ones, for gain in barter and trade; visits arranged by the grape vine telegraph or a code of signals; but visits which have brought to our Southern country countless cost in money and untold misery and woe and death. Respectfully,

C. P. Wilkinson, Resident Physician.

The Quarantine Methods a Constant Menace to the Mainland.—Dr. J. W. Belden of New Orleans, a homeopath practitioner of good standing, sends the following statement to the *Daily Picayune*, which, if true, throws a side light on the methods of quarantine at Ship Island:

"I did go over to Ship Island during the month of May last and contracted a case of yellow fever. I usually spend my vacations every summer over at Biloxi and a place over there. I am fond of piscatorial sports and as the fishing in Ship Island harbor is fine, I usually go over there to fish Spanish mackerel. During the month of May I made four excursions over to Ship Island and on the occasion of my last visit, late in the month of May, I met two of the nurses from the quarantine hospital and they informed me that they had several yellow fever cases in the hospital. I asked them if they did not fear spreading the disease among the people who were present on the wharf where the bumboat from Biloxi usually landed. The nurses laughed and said there was no fear as they had had a bath just before they joined the party of excursionists, but I was at the time of the opinion that this was not sufficient, as their clothing had not been disinfected. I said nothing at the time and a day or two afterward came to this city.

"Within nine days after this episode I was taken suddenly with a chill, my head ached and I suffered from severe pains in the back accompanied with nausea, although just before this I had been in perfect health. My temperature went up to 104 degrees and I sent for Dr. Charles R. Mayer. I had never had any experience in yellow fever cases, and neither had Dr. Mayer, but for two days I had a very high fever. After that terrible prostration followed and there was a total collapse.

"Six days after I was taken sick I returned to Biloxi, and, meeting Dr. Mayer, he remarked that my eyes were very yellow and said that my liver was in a fearful state and advised me to take a remedy. Since then I have had experience in yellow fever cases, and I am convinced that I had a Simon-pure case of yellow fever, and that I received the infection at Ship Island. I had all the symptoms, the headache, the backache, the high temperature, the gastric disturbance and the prostration which invariably follows an attack of yellow fever."

Dr. Belden said that the quarantine regulations at Ship Island had been very lax and that there was free communication with the mainland. On one visit which the doctor made to Ship Island, there were fifty-two vessels lying in the harbor waiting to load lumber, and the tug or bumboat made three trips daily from the mainland to the island, carrying a large number of passengers each trip. On the wharf where the tug landed its passengers, the nurses from the hospital as well as the employes, and ofttimes the crews of the vessels, resorted to hear the news of the day or to enter into conversation with the people from the mainland.

Dr. Belden said that he was a very sick man, and, although not being able to diagnose his own case, yet he thought the attack a very peculiar one. Recently he met Dr. Matas and described his symptoms accurately, and then gave him a brief history of the case. Dr. Matas immediately pronounced it a case of genuine yellow fever, and asked Dr. Belden to write up a history of the case and give it to him, which he promised to do. Subsequently he met Dr. E. S. Lewis and made a similar statement to him, and Dr. Lewis concurred in the opinion of Dr. Matas. He thought it was outrageous to put the pesthouse on Ship Island. It was infamous. Vessels come within a mile of the island and the place is frequented by fishermen and visitors from the mainland. There are no restrictions regarding communication with the nurses or employes of the pesthouse, nor yet of the crews of vessels, which, coming possibly from the foreign infected ports, can, and do, spread the disease. He was of the opinion also that the infection was carried in currents of air and would be dangerous even if the nurses did not have any communication with the people.

At the present time he felt better than he had felt in years, and, although he had tended many yellow fever cases since the prevailing fever was declared to be yellow fever, yet he had not been taken sick. He was convinced that he is now immune, for if he had not had yellow fever early in the season, he says he feels satisfied that he would have taken it from one or the other of the patients whom he attended. He says that he had patients who had the black vomit and he was covered with the vomit, yet he had not taken the fever, which corroborated his opinion as to the nature of the disease which he had in June last.

The only thing about it that was strange was that none of his family caught the infection from him. He said that he was very liable to catch fevers or any other prevailing disease and is usually among the first to take any sickness going around, hence he feels sure that he had the yellow fever and as far as he knows it was the first case in this city this year.

He earnestly advocates the removal of the quarantine from Ship Island to some more remote locality, and one not so easily accessible as is Ship Island.—*New Orleans Daily Picayune.*

Yellow Fever.—Our record last week closed with October 26. Since that date the dispatches have reported as follows: October 27, New Orleans, 52 new cases and 11 deaths; Biloxi, Miss., 12 new cases and 1 "suspicious" case; Scranton, 9 new cases and 1 death; Atlanta, Ga., 1 new case; Memphis, Tenn., 5 new cases and 2 deaths; Cayuga, Miss., 2 new cases, and 1 new case near Raymond. October 28, New Orleans, 65 new cases and 8 deaths; Clinton, Miss., 1 new case and 1 death; Edwards, Miss., 5 new cases; Cayuga, 1 new case: Mobile, Ala., 6 new cases and 4 deaths; Whistler, Ala., 1 death; Flomaton, 4 new cases; Montgomery, 9 new cases; Lapine, 1 death; Baton Rouge, La., 1 new case; Bay St. Louis, Miss., 12 new cases; Memphis, Tenn., 8 new cases and 2 deaths. October 29, New Orleans, 5 new cases and 5 deaths: Jackson, Miss., 10 new cases and 1 death; Mobile, Ala., 5 new cases and 3 deaths. October 30, New Orleans, 31 new cases and 6 deaths; Edwards, Miss., 1 new case: Nittayuma, 1 new case; Mobile, 9 new cases and 2 deaths. Heavy frosts are reported in Mississippi, but none at New Orleans. October 31, New Orleans, 35 new cases and 5 deaths, making a total of 1,706 cases with 170 deaths in that city; Montgomery, Ala., 6 new cases; Mobile, 11 new cases; Jackson, Miss., 2 new cases; Clinton, 2 new cases; Biloxi, 3 new cases; Memphis, Tenn., 3 new cases. November 1, New Orleans, 38 new cases, 12 deaths; Mobile, Ala, 9 new cases; Montgomery, 1 new case, 1 death; Bay St. Louis, 6 new cases; Biloxi, 6 new cases, 1 death; Durant, 1 death; Edwards, 1 new case; Memphis, Tenn., 2 new cases, 1 death; Nittayuma, Miss., 3 new cases, 1 death; Pascagoula, 3 new cases: Scranton, 3 new cases, 1 death. November 2, New Orleans, more hopeful on account of prevailing cooler weather. 33 new cases. 6 deaths; Montgomery, Ala., 2 new cases; Greensboro, 2 deaths; Speigners, 1 suspicious case among the State prisoners; Memphis, Tenn., 3 new cases, 2 deaths.

A Plea for a Department of Public Health.—At a meeting of the board of trade and transportation, held in this city on October 13, Dr. Warren E. Anderson of Pensacola, formerly a member of the Florida State Board of Health, read a paper advocating the creation of a United States Department of Public Health independent of the treasury, war, navy or any other department of the national government. He said that "uniformity of quarantine laws and regulations can be obtained only through federal control. This is greatly to be desired, as it alone can prevent the wild, reckless and absurd shotgun quarantines, allay panics, restore confidence and prevent commercial rivalry of seaports, in their greed for trade, from endangering the public health of the entire country. The State should be represented in the national health councils, and the laws there made should be executed through this representative. All sanitary or quarantine officials should be residents of the State whose health interests they are to protect, and no official should be appointed in the way of political preferment, but only upon personal qualifications approved by commercial organizations, where such exist. The foreign tonnage tax should be applied to the purposes of quarantine, and thus relieve the people and the commerce of the country from the heavy and unjust burdens laid upon them by the present system of health protection. The marine-hospital service should be remanded to the performance of that duty which it has so faithfully done for the past one hundred years—the care of sick and disabled American seamen. A failure upon the part of the Federal Congress to provide the citizen with adequate protection against the invasion of imported disease and the prevention of the recurrence of such scenes as are being enacted along the lower Mississippi Valley and the gulf coast, will be regarded as a national calamity."—*Medical Record*, October 30.

National Bureau of Health.—According to the *Medical Record*, Dr. A. Jacobi made the following motion at the recent meeting of the New York Academy of Medicine, October 21, which was carried unanimously:

"That the New York Academy of Medicine authorizes its president to call the committee appointed years ago, and never discharged, and direct it to resume its interrupted labors and to report to the Academy of Medicine, for presentation to the Congress of the United States for adoption, the old bill, or a new bill, or to support a proper bill offered by great medical or commercial bodies, contemplating the centralization under the National government of the means to protect efficiently the health of the American people against the importation and dissemination of contagious diseases."

SOCIETY NEWS.

The Sixth International Congress against the abuse of alcohol completed its labors at Brussels, September 3. Addresses were presented by Forel, Lejeune, L. Frank, Miss Gray, Destrees, Mahaim and others, all leaders in the struggle against the abuse of alcohol. The importance of an active propaganda was strongly emphasized as the first stage in the work, arousing and educating public opinion. The second stage is legislation providing for compulsory official education in regard to the evils of alcoholism, and the third stage is legislation dictated by an enlightened and convinced public opinion. Certain nations (Norway), after passing through all these stages, are now completely freed from the scourge. Others (Switzerland, Germany), are entering the legislative stage, to which Belgium is also aspiring. The advisability of a constant literature on the subject was recognized, and the suggestion made that, instead of founding new organs, special editions of some established organ might be issued as demanded. The paralyzing effect of alcohol, demonstrated by new instrumental tests, was presented in a forcible light. A colored African bishop portrayed the frightful ravages caused among his compatriots by the impure alcohols sold to them by certain European nations. At the banquet wine, cider and beer without alcohol were served as beverages and extolled for their extremely nutritive properties and agreeable flavor, although too sweet, perhaps, to suit the general taste. The complete report of the proceedings can be obtained from the Secretary, Dr. de Vaucleroy, 290 Avenue Louise, Brussels. The next Congress will convene at Paris in 1899.

The New York State Association of Railway Surgeons will hold its seventh annual meeting, New York City, November 16. The following papers are announced: "Neuropsychic Manifestations Subsequent to Fractures or Dislocations," by Thomas H. Manley, New York; "A Review of So-called Traumatic Neuroses," by W. B. Outten, St. Louis; "Alleged Injuries," by W. J. Herdman, Ann Arbor; "Medico-Legal Features," by Hon. L. L. Gilbert, Pittsburg; An Address, by Hon W. H. Baldwin, Jr., Pres. L. I. R. R.; "Medical Expert Testimony," by Clark Bell, New York; "Internal Injuries," by C. B. Herrick, Troy; "Primary Dressings," by C. S. Parkhill, Hornellsville; "Primary Hospital Treatment of Those Injured *en Masse*, by John F. Burns, Brooklyn; "Asepsis in Emergencies," by W. C. Wood, Gloversville; "Some Newer Antiseptics, Their Uses in Railway Surgery," by F. A. Palmer, Mechanicsville; "Intestinal Toxemia as a Factor in Retarding the Healing of Wounds," by Harvey P. Jack, Canisteo; "Injuries to the Nervous System in Railway Accidents," by Charles R. Phillips, Hornellsville.

BOOK NOTICES.

Bulletin of the Harvard Medical Alumni Association, No. 11. Paper, 76 pages. Boston: 1897.

This volume is a report of the seventh annual meeting, held in Boston June 29, 1897. The typography and workmanship, with the excellent paper, combine to make this a very attractive number.

Transactions of the Michigan State Medical Society for the year 1897. Cloth, 528 pages. Grand Rapids: 1897.

This is Vol. xxi of the "Transactions" and contains various reports, addresses on surgery, gynecology and medicine, the constitution, list of members and list of the medical societies in Michigan. In the Section on Medicine and Obstetrics there are fourteen papers; in the Section on Gynecology and Abdominal Surgery, eight, and in the Section on Surgery, fifteen papers, printed in full, in many cases with discussion. The volume is a credit to the Society, both in contents and workmanship, and the various papers contain much of value to the practitioner.

Seventeenth Report of the State Board of Health of Wisconsin. Paper, 52 pages. Madison: 1897.

The report contains the laws relating to vital statistics, transportation of the dead, adulteration of foods, drugs, bakeries, etc. The secretary, U. O. B. Wingate, M.D., contributes "Some Thoughts Relative to Sanitary Legislation." "Formaldehyde as a Disinfectant" is also considered and a "Report of the Committee of the American Public Health Association on the Cause and Prevention of Diphtheria."

The Vital Statistics of Massachusetts, 1856-95. Paper, 811 pages.

This is from the "Twenty-eighth Annual Report of the State Board of Health of Massachusetts" for 1896 and contains much of value concerning vital statistics and in handy form.

NECROLOGY.

Lyman T. Collar, M.D., Hingham, Wis., October 22, aged 52 years.——Jacob Hay, M.D., York, Pa., October 18, aged 54 years.——John May, M.D., New Holland, Ohio, October 20, aged 82 years.——A. M. Ross, M.D,, Montreal, October 27, aged 65 years, one of the founders of the Society for the Discussion of Physiologic Knowledge in 1881.——George F. Mather, M.D., Shenandoah, Pa., October 22, aged 57 years.

MISCELLANY.

Bureau of Clinical Medicine and Surgery.—There has been established in Philadelphia, at the northeast corner Thirteenth and Locust Streets, a bureau of clinical medicine and surgery, with telephone connection, in charge of a clerk, whose duty it shall be to receive and post notices of the daily work in the branches of surgery and medicine taking place at the different hospitals. This can be accomplished by notice to the bureau by postal card or telephone. By this means it is hoped that the numerous physicians who visit the city may be able to take advantage of the great clinical facilities afforded by the hospitals of Philadelphia. A physician calling at the central bureau is thus able to ascertain what medical or surgical work may be going on during that day in any one of the different hospitals. Physicians visiting Philadelphia are cordially invited to use these facilities.

The Iodin Reaction in the Blood has a differential value, according to M. Goldberger and S. Weiss, who have demonstrated that it indicates a suppurating process. In case of progressing or active suppuration the leucocytes stain brown with the Ehrlich iodin mucilage test: Iodi subl. 1; potass. iodi., 3; aq. dest., 100; gumm. arab., q. s. ad consist. syrup. The polynuclear neutrophilous cells are almost exclusively affected, and the intensity depends upon the rapidity of the abscess formation. The reaction disappears after incision and as the abscess becomes cold. The test is not reliable when there is concomitant pneumonic infiltration or after prolonged narcosis.—*Wien. Klin. Woch.*, June 24.

Hot Air Cauterization.—Holländer of Berlin applies hot air at 300 degrees C., directly to the skin, in the treatment of lupus, using a small apparatus which he can regulate at will. The effect is not mechanical, like the Paquelin, and there are no contractions in the scar. As the heat is applied the sound tissue contracts in complete ischemia, while the lupus tissue, in which the vessels are destroyed, is unable to contract and thus receives the full effect of the heat. In the scab formation circulation is restored in the sound tissue, while the necrosed lupus tissue is thrown off. He has been successful in many old, chronic cases with patches on the face as large as a hand, and no relapses in the year since, and he recommended at the Moscow Congress this treatment in high terms, with an interesting demonstration, especially in old and extensive cases.

Railway Accidents.—The statistics submitted show that the number of railway employes killed during the year ending June 30, 1896, was 1,861, and number injured was 29,969. These figures indicate an increase of 50 in the number killed and of 4,273 in the number injured, as compared with the preceding year. The number of passengers killed was 181 and the number of passengers injured 2,873, being an increase of 11 in the number killed and of 498 in the number injured. The number of persons other than employes and passengers killed was 4,406 and the number injured 5,845. These figures include casualties to persons reported as trespassers, of whom 3,811 were killed and 4,468 were injured. From summaries showing the ratio of casualties it is found that for every 444 men employed on railways 1 was killed, and for every 28 men employed 1 was injured. A similar comparison as to trainmen shows that 1 trainman was killed for each 152 trainmen employed and that 1 trainman was injured for each 10 trainmen employed. The number of passengers carried for 1 passenger killed was 2,827,474 and the number of passengers carried for one passenger injured was 178,132. As showing in another way the immunity of passengers from accidents, the report gives ratios based upon the number of miles traveled, from which it appears that 72,093,963 passenger-miles were accomplished for every passenger killed and 4,541,945 passenger-miles for every passenger injured.—*Interstate Commerce Com. Report.*

Hospital Abuses in St. Louis.—It has been stated in the *American Journal of Surgery and Gynecology* that 400 well-qualified physicians in St. Louis are practically destitute. A committee from the St. Louis Medical Society appointed to examine into the abuses of medical charity, reported that the dispensary of the St. Louis Medical College is guilty of treating free applicants who are well able to pay. This dispensary treats over 2,000 cases a week. The committee also found that the dispensary of the Missouri Medical College is the greatest offender against the well being of the medical profession and the community in general by treating free a large number of patients who are well able to pay. It is also stated that many of the members of the faculties of these two colleges are upon staffs of hospitals which employ "runners" to increase their business. It is to be hoped that the exposure by this committee will be followed by some changes for the better in the city, which, next to New York, seems to be the greatest sufferer in this regard.

Treatment of Yellow Fever with Chlorin Water.—Dr. A. Simoes announces that he has reduced the mortality from yellow fever to 8 per cent. in his private practice, and 15 per cent. in hospital cases, by treating the disease with chlorin water, for which he claims marvelous virtues. He asserts that it is the best gastro-intestinal disinfectant, not only destroying the germs but rendering the organism an unfavorable soil for their further virulent development or neutralizing the ptomains. It has a marked tonic effect on the heart and kidneys and acts as an astringent and hemostatic, but its principal value is its specific effect on "black vomit," which is arrested by the first doses. He administers a purgative, then sodium salicylate combined with aconite or antipyrin, followed by quinin, resorting to the chlorin water in the second or third stages and supplementing it with artificial serum in certain cases of anuria. *O Brazil Medico* (September 15) comments rather incredulously on this therapeutic apotheosis of chlorin water, mentioning incidentally that Simoes is a zealous convert to Freire's discovery of the microbe of yellow fever.—"Tratamento da febbre amarella pela agua chlorada," Angelo Simoes, M.D., Campinas. Typ. Besnard Freres; 1897, pp. 101.

Elimination of Bacteria through the Kidneys.—The results of former research (Biedl, Kraus, et al.) demonstrated that microorganisms (staph. py. aur., bact. coli, anthrax bac.), introduced into the veins were eliminated through normal kidneys, commencing to appear in the urine in a few minutes. Also that stimulation of the urinary secretion favored the elimination. Klecki confirms the former statement, but in a series of experiments with smaller amounts of cultures than hitherto used, corresponding more to the natural processes, he failed to discover any favorable effect of increased diuresis on the elimination of the bacteria, even with caffein, theobromin, or 500 c.c. normal salt solution. The beneficial effect of salt solution in infections must therefore be due to attenuation and increased elimination of the toxins. He adds that the kidneys only eliminate a fraction of the total number of bacteria; they may still be circulating in the blood after all renal elimination has ceased. —*Wien. klin. Woch.*, August 26.

The Value of Vibratory and Tremolo Massage should be impressed on every practitioner and student, as Gambara remarks in an article on the subject in the *Gazz. degli Osp. e delle Clin.* of August 1. The indications are the same as for electrotherapeutics in all acute or chronic diseases of the nervous and peripheral system, whenever massage could be applied to advantage. It is remarkable in its curative effect in affections of the ears, of the mucous membrane, nasal, gastric, intestinal, and of the genito-urinary system; also in chronic cutaneous troubles. It is not an empiric treatment, but is based on rational and physiologic grounds, as it acts on the anatomic elements, and promotes the transformations of matter better than any other therapeutic measure, while removing the morbid refuse. He recommends especially Professor Boschetti's small hand apparatus, which transmits a rapid and almost silent rotary movement to an articulated metal rod or flexible cord producing from 4,000 revolutions a minute upward. It can be connected with a gas or electric motor if desired. An eccentric changes the motion from a rotary to a tremolo at will. The rotary or vibratory movement is transmitted to the tissues in parallel planes like waves of sound, and is communicated onward in the same way, while the tremolo affects them like the concentric ripples that spread when a stone is thrown into a quiet pool. The tissues thus feel the effect in every direction, and the massage is much more effective.

A New Centrifuge for Medical Purposes.—There has recently been perfected a centrifugal machine for the rapid examination of urine, blood, sputum, milk, water, etc. The fluids are contained in glass tubes which are rotated horizontally by means of a set of hardened bronze gears having spirally cut teeth. The speeds required vary from 2,000 to 12,000 per minute, hence the spirally cut teeth are a great advantage, as they very materially reduce the friction and noise generated by the rapid rotation and thus increase the speed attainable, also the wearing qualities. The reason for the saving effected, lies in the fact that three teeth always come in contact at once and in a shearing manner, so as to prevent all back lash, etc. The gearing and axles are contained in a circular metal case four inches in diameter and one inch thick. In use the instrument is clamped to the table by a screw clamp. For the precipitation of sediments in urine, the urine is contained in two glass tubes, each having a capacity of 15 c.c. of fluid. One of the tubes is plain and is intended for the collection of sediment for microscopic examination. The other tube has the first 10 c.c. graduated into 100 parts, the 15 c.c. point being also indicated by a graduation. In this tube 10 c.c. of the urine to be examined are placed and 5 c.c. of the proper re-agent to cause the precipitation of the substance which it is desired to determine, is then added. After centrifugation, the substance (chlorids, phosphates, sulphates, albumin, etc.) will be found collected in the distal end of the tube and the per cent. may be read direct from the scale. A neat manual of "Centrifugal Analysis" minutely describing the various methods employed in the examination of blood, urine, sputum, milk, water, etc., is sent free upon request by the Bausch & Lomb Optical Co., Rochester, N. Y.

How to Maintain the Balance of Nitrogen in Nephritis.—In an article in the *Gaz. d. Osp e d. Clin.*, July 25, Prof. E. Maragliano emphasizes the importance of resting the kidneys by reducing the nitrogenous substances ingested, to the lowest amount compatible with non-consumption of the organic tissues. Many have endeavored to determine this minimum, but their failures should not discredit the principle, which is vital. He has solved the problem by individualizing, with careful tests. He begins by limiting the patient to a half liter of milk a day. If the amount of nitrogen eliminated is more than the amount that corresponds to the albuminoids ingested, which is usually the case, it signifies that there has been consumption of organic albuminoids. The quantity of milk allowed should then be increased to add the amount of albumin corresponding to the excess in the nitrogen eliminated. Five days at least, are required for the test, passing from a richer to a poorer alimentation, but two or three are enough when the change is from a poorer to a richer. He supplies the necessary amount of calories (considering 25 calories per kilog. a low average), by adding sugar and rice cooked in milk or in water with fat in the sauce. Every effort must be made to keep the nitrogen ingested within the limits indicated by the test. This minimum represents the maximum of rest that can be conceded to the kidney; it can not be mathematically fixed, but varies from time to time, requires a repetition of the test at least once a month, with daily determination of the density of the urine as a slight guide in the meantime. It is wise to note the fecal with the urinary elimination, but when not practicable it can be approximated by remembering that in normal persons it varies from one-half to one and one-half in twenty-four hours, and the larger amount is more apt to be correct in nephritis. In all acute cases of nephritis the physician will not err if, even without testing, he limits the patient to one-half to one liter of milk a day with 200 grams of rice and 25 to 50 grams of sugar until the acute stage is past. In addition to the above, Maragliano restricts the diet one day in every eight, to a scant liter of milk, and has the patient drink one and if possible two liters of alkalin mineral water, obtaining by this means the combustion of accumulated nitrogenous residue and its elimination, and obviating auto-intoxication, which is usually the cause of death in nephritis.

Infection Through the Air.—C. Flügge reports (*Ztft. f. Hyg. u. Infect.*, Vol. 25, No. 1), the results of much research in regard to the transmission of germs through the air. Dust from matter containing bacteria always consists partially of fragments so minute that they float in the air of a quiet room for more than four hours, and the slightest current of air will waft them about. He also states that tiny drops of moisture containing bacteria pass into the air even in closed rooms from the ordinary manipulations and float for five hours, and are transported by a current no stronger than 0.07 m.m. for a horizontal draught or 0.1 m.m. for an upward current. The dissemination of these transportable drops is of great importance in regard to the secretions of the mouth and nose, especially in case of tuberculosis, influenza, diphtheria, etc. He found by repeated tests that plates of agar become covered with colonies of bacteria at a distance of several yards, from persons speaking loudly and energetically. Coughing produced a still more rapid and abundant colonization, while the plates showed no growth when the person spoke low and quietly. He does not consider dry particles floating as dry dust in the air a serious menace for the infection of wounds during operations, as the staphylococcus aureus and albus in these conditions are not sufficiently virulent to colonize agar plates; all his experiments in this line were negative. But he emphasizes the danger to be apprehended from the drops of moisture disseminated from the secretions of the mouth and nose of the persons present at the operation, as they speak, sneeze or cough. The pyogenic bacteria are frequently found in the mouth of perfectly healthy persons, and decayed teeth are a mine of all sorts of bacteria. These microbes have not been attenuated by drying, but are moist and often extremely virulent. Distance from the operating table does not prevent the germ-laden drops of moisture from reaching the patient or some following case or alighting on the instruments. The patient himself may infect the field by heavy breathing, etc. Mikulicz's "Transcendental Surgery," described page 201 of the Journal (gloves and mouth screens), was inspired principally by these experiments of Flügge, with which he was familiar.—*Cbl. f. Chir.*, October 2.

The Dixon Case.—The decision of the Illinois supreme court in the Dixon case will be disappointing in the extreme, but as it is held to be law, we suppose we will have to make the best of it until the statutes shall afford relief. In the supreme court of Illinois a decision was handed down which is of great interest to physicians and others who may be called upon to give expert testimony in court. It is held by many professional men that they can not be compelled to give a professional opinion without a reasonable compensation, and in support of this they quote that portion of the constitution which declares that no person shall be deprived of property without due process of law. The case in which the decision was handed down is an appeal of Dr. J. Norman Dixon from a judgment rendered against him by Judge Creighton, of the Sangamon circuit court, some time ago, in which it was agreed a test should be made. Dr. Dixon was called to give expert testimony in a damage suit for personal injury against the city of Springfield. He refused to testify unless he was paid a professional fee of $10. Judge Creighton fined him $25 for contempt of court and the case was appealed to the appellate court, where Judge Creighton's judgment was affirmed. The case then went to the supreme court, where the judgment was again affirmed. The briefs in the case were prepared by State's Attorney James M. Graham, and the ground taken was that professional knowledge of the kind required in expert testimony is not properly within the meaning of the constitutional provision, as it can not be given away nor alienated from the person possessing it, and that in the exercise of the right of the court to summon witnesses and compel them to testify no distinction can be made between kinds of knowledge without endangering the ends of justice. This view of the case was upheld by the appellate court, and now the supreme court affirms it. Judge Creighton's decision attracted general attention when it was announced and called forth the strongest condemnation from members of the medical profession. However, he is now upheld by the highest judicial tribunal in the State.

Deaths from Gangrenous Varicella.—An annotation in the London *Lancet* for October 9, adverts to two fatal cases of varicella that have been reported by two American physicians in the *Archives of Pediatrics*, September; one case having been described by Dr. Silver of New York City and the second by Dr. Lockwood of Baltimore. The case of the latter was a well-nourished female child two years of age which when first seen exhibited a well-marked varicellous eruption. On the next day a wide zone of dusky red dermatitis occupied nearly the whole surface of the trunk. Rapid ulceration of the spots within this area ensued. The contents of many of the vesicles became hemorrhagic. Bleeding from the mouth and nose occurred and blood was extravasated in the skin over the pubes and about the genitals. The gangrenous spots varied in depth, and in size from a pea to a surface measuring one inch by two inches. They often occurred where there were no varicella vesicles. On the trunk were large patches where the epidermis only was removed, exposing purplish dry surfaces. These were due to the dermatitis, and did not radiate from the chicken-pox vesicles. The deeper spots showed a dry, hard, black eschar in the center, an ulcerating border, and an elevated inflamed edge. The left eye was closed from swelling and ulceration of the upper lid, and there was free purulent discharge from between the lids. The child emitted an extremely fetid odor. Death took place on the eighth day, apparently from bronchopneumonia; but satisfactory examination of the chest was not possible. The other case was that of a boy in good health, two years of age. The illness began with diarrhea, which was followed by a temperature of 103 degrees F., lethargy, and a convulsion. On the fourth day the body was covered with the characteristic rash of varicella. The mucous membranes of the mouth and conjunctiva were congested. On the third day of the eruption circles of congestion from one-fourth to one-half inch in width were noticed around several of the spots, which had become black and depressed in the center. Next day three gangrenous areas, measuring from one to two and one-half inches across, appeared on the neck. On the following day both eyelids were so much swollen that they could not be opened and there was a profuse discharge of blood and serum from the mouth and nose. The urine contained abundant albumin and numerous granular casts. The child died in the evening soon after a convulsion. It is curious that varicella, the mildest of all the infectious diseases, should present such a grave complication. Mr. Hutchinson, who first described the disease, attributed the occurrence of the gangrene to idiosyncrasy, as it usually occurred in healthy children. Mr. Barlow, however, denies this and asserts that in none of his cases were the children healthy. A second infection by some microbe supervening on the varicella has also been offered as an explanation, but evidence on this point is wanting.

The Chemistry of Bacterial Disinfection.—The *Cbl. f. Chir.* (October 20) reviews the recent important work of B. Krönig and T. Paul in this line. They state that: 1. Comparative tests should be made with equimolecular quantities, as a "percentage" is unreliable in précise research. Among their conclusions we note that the disinfecting power of solutions of the metallic salts depends on the specific properties of the salts and of the dissolving medium as well as on the concentration of the metal. 2. The effect of the halogenous combinations of mercury varies in proportion to their degree of dissociation. 3. The disinfecting power of aqueous solutions of mercuric chlorid is diminished by the addition of the halogenous combinations of the metals and hydrochloric acid, probably due to the retarded electrolytic dissociation. 4. The disinfecting power of mercuric nitrate, mercuric sulphate and mercuric acetate is materially increased by the addition of a moderate amount of sodium chlorid. 5. Acids disinfect in proportion to their electrolytic dissociation, that is, in proportion to the concentration of the hydrogen ions contained in the solution. 6. The bases, potassium, sodium, lithium and ammonium hydroxyds disinfect in proportion to the concentration of the hydroxyl ions contained in the solution. Hydrogen ions are more powerfully toxic for anthrax spores and the staph. pyog. aur. than hydroxyl ions at the same concentration. 7. The disinfecting power of the halogens, chlorin, bromin, iodin, decreases in proportion to increasing atomic weight. 8. Nitric acid, dichromic acid, chloric acid, hypersulphate and permanganate disinfect in proportion to their rank in the series of oxidating elements arranged according to their electric properties. Chlorin has a very strong specific disinfecting effect. 9. The disinfecting power of various oxidating elements is materially increased by the addition of halogen-hydrogen-acids, such as hydrochloric acid added to potassium permanganate. 10. Their experiments confirm Scheurlen's announcement that solutions of phenol disinfect better when salts are added. Also that substances dissolved in alcohol, methyl alcohol and ethyl ether have scarcely any effect upon anthrax spores. 11. The disinfecting power of aqueous solutions of silver nitrate and mercuric chlorid is materially increased by the addition of certain definite amounts of ethyl alcohol (50 per cent. for arg. nitric.; 25 per cent. for sublimate), methyl alcohol and acetone. 12. The disinfecting power of aqueous solutions of phenol and formaldehyde decreases with any addition of ethyl or methyl alcohol. Bouillon, gelatin, organic fluids, also diminish the disinfecting power of aqueous solutions of the metallic salts. 13. Conclusions in regard to the power to prevent the development of bacteria drawn from bactericidal power of a substance are unreliable.

Societies.

The *following meetings are noted*:

Connecticut.—New Haven County Medical Association, New Haven, October 21.

Indiana.—Vanderburgh Medical Society, Evansville, October 19.

Kansas.—Eastern Kansas Medical Society, Bonner Springs October 30.

Maryland.—Baltimore County Medical Association, Towson, October 21.

New York.—Binghamton Academy of Medicine, October 19; Medico-Legal Society, New York City, October 20.

Ohio.—Cleveland Medical Society, October 22; Lorain County Medical Society, Lorain, October 26. Northern Ohio District Medical Society, Sandusky, October 28.

Wisconsin.—Fox River Valley Medical Society, Oshkosh, October 16.

Washington.

Health of the District.—The report of Health Officer Woodward, for the week ended October 23, shows the total number of deaths to have been 91, of which number 51 were white and 40 colored. Among the principal causes of death were 12 of the nervous system, 7 of circulatory; 19 from consumption. There were 2 fatal cases of typhoid fever and 2 of diphtheria.

Medical Society.—At the meeting of the Medical Society, held on October 27, a number of cases and specimens were presented, as follows: Dr. Allen, fibrinous bronchitis; Dr. Walter Reed, splenic leukemia; Dr. Tompkins, tumor of the cerebellum; Dr. Behrend, sarcoma of the uterus, and Dr. Acker, specimens from general tuberculosis.

Detroit.

Wayne County Medical Society.—At the regular meeting of this Society, October 21, Hal C. Wyman, M.D., read a paper on the subject of "Appendicitis." His theory of its etiology is that it is caused by a special bacillus which accepts the soil of the appendix for its ravages, as certain bacilli accept certain localities and produce typic diseases, for example, the typhoid bacilli, which attack Peyer's patches, etc. The inflammation of the appendix begins in the mucosa and may end there, or the disease may go on to inflammation with its necessarily serious results, indicated by an increase of pain, tenderness and rigidity of the region involved. Symptoms have been known to be absent until death was imminent, therefore early operation is indicated. The case often comes too late to the surgeon. As a rule it is the complication which kills the patient, and not simply the sloughing appendix. The most serious complication is obstruction of the bowel. It is a fact that no death occurs from appendicitis in which there is not an obstruction of the bowel. This complication should be treated by an enterostomy. Loss of heat to the body of the patient from prolonged operation is another serious complication which should be combated by the application of dry heat to the trunk. The practice of applying towels wrung out of hot water to the exposed intestine is harmful, for the reason that the water so applied evaporates rapidly and so causes a rapid loss of heat. Diagnosis is easy and simple. When in doubt, and the patient's condition is serious, incision should be made to find cause.

CHANGE OF ADDRESS.

Borck, E., from St. Louis, Mo., to Red Bud, Ill.

Cole, A. M., from 173 North Pa. Avenue to 24 East Ohio, Indianapolis, Ind.; Calvin, J. P., from New Castle to Eureka, Ala.; Craig, W. H., from Glendora to North Ontario, Cal.

Eastman, C. A., from Exeter, N. H., to Danvers, Mass.

Frank, J., from Ozark, to Carondelet, Ill.; Foreman, J. M., from 4126 Easton Avenue to 2867 Easton Avenue, St. Louis, Mo.; Fletcher, W. B., from 713 Fletcher Avenue to 218 North Avenue, Indianapolis, Ind.

Hollnger, J., from 1373 N. Clark Street, to 311 Sedgwick Street, Chicago, Ill.; Harmison, D. C., from Bath to Havana, Ill.

Jump, E. D., 1251 So. 47th Street to 1631 Chester Avenue, Philadelphia.

Hackett, J. C., from Le Mars, Iowa, to Lacygne, Kan.

Kirkpatrick, T., from Topeka to Garnett, Kan.; Kilbride, J. S., from Dawson, Minn., to Emmetsburg, Iowa.

Lockwood, W. D., from Columbia to Stockyards, Mo.

Munn, W. P., from 709 11th Street to 2401 Colfax Avenue E., Denver, Colo.

Naughton, M. T., from 1532 Indiana Avenue to 1725 Ashland Avenue, Chicago, Ill.

O'Reilly, P. S., from 2829 Lucas Avenue, to 2839 Lucas Avenue, St. Louis, Mo.

Ramsey, R. T., from Danville to London, Ky.

Tittin, A. J., from Harris to Maynard, Minn.; Thomas, F. W., from Marion, Ohio, to Denver, Colo.

Let us have a Department of Public Health!

LETTERS RECEIVED.

Anderson, W. E., Pensacola, Fla.; Arlington Chem. Co., Yonkers, N. Y.

THE PUBLIC SERVICE.

Army Changes. Official List of Changes in the Stations and duties of officers serving in the Medical Department, U. S. Army, from October 9 to 15, 1897.

First Lieut. Thomas J. Kirkpatrick, Jr., Asst. Surgeon U. S. A., is granted thirty days' extension to leave of absence.

Major W. C. Shannon, Surgeon U. S. A., sick leave of absence further extended six months.

Lieut.-Col. Charles Smart, Deputy Surgeon-General U. S. A., and Capt. William H. Arthur, Asst. Surgeon U. S. A. are detailed to represent the Medical Department of the Army at the twenty-fifth annual meeting of the American Public Health Association, to meet at Philadelphia, Pa., Oct. 26 to 29, 1897.

Major Alfred C. Girard, Surgeon U. S. A., is detailed to represent the Government of the United States at the Ninth International Congress of Hygiene and Demography, to be held at Madrid, Spain, April 10 to 17, 1898.

The Journal of the American Medical Association

Vol. XXIX. CHICAGO, ILL., NOVEMBER 13, 1897. No. 20.

ADDRESS.

CHAIRMAN'S ADDRESS.

Delivered in the Section on Diseases of Children at the Forty-eighth Annual Meeting of the American Medical Association, at Philadelphia, Pa., June 1-4, 1897.

BY JOHN A. LARRABEE, M.D.
LOUISVILLE, KY.

In consideration of the event of the semi-centennial meeting of the American Medical Association, I have deemed it proper to depart from the customary style of the annual address in order to give, as far as possible, a correct history of the Section over which I have the honor to preside. To accomplish this I have placed myself in communication with some of the older members of the Association and with Dr. William B. Atkinson, the Permanent Secretary. The following letters, from Dr. A. Jacobi of New York, and Dr. T. M. Rotch of Boston, will throw some light on the origin of our Section:

New York, Feb. 5, 1897.

John A. Larrabee, M.D.

Dear Doctor:—There is no history. We just did it. As I felt in some doubt I wrote to Dr. Rotch and as the enclosed letter shows, he knows just as little. It is a clear case of spontaneous generation, the Section was in the air, and we were present when it condensed. That is all.

Very sincerely yours, A. Jacobi.

197 Commonwealth Ave., Feb 2, 1897.

Dear Dr. Jacobi:—I only know that you were asked by a number of men to found the Section and be its first President at the meeting in Richmond. You asked me to be your Secretary and I accepted with pleasure and listened to your words of wisdom. Sincerely yours, T. M. Rotch.

It was not until the year 1880 that the Section on Diseases of Children became independent. Previous to this time the work of this Section was done in the Section on Obstetrics and Diseases of Women. At this meeting of the Association, which was held in New York City, an address on the Claims of Pediatric Medicine was delivered by Dr. Jacobi. Dr. S. C. Busey offered a resolution creating this the sixth Section of the Association, and Dr. A. Jacobi was made Chairman and Dr. W. H. Bradford of Massachusetts, Secretary. Thus it will appear that our Section is the sixth legitimate offspring of the American Medical Association. Dr. Busey of Washington, D. C., was the accoucheur on this occasion and Dr. Jacobi stood godfather for the tender infant. Many distinguished worshipers were also present and brought precious spices and rare incense to lay at the feet of the newborn babe. Papers were read by Busey on Chronic Bright's disease in children, caused by malaria; by James S. Green of New York, on a Case of congenital occlusion and dilatation of the lymph channels; by Jacobi, on Atrophy of a fetal liver, and Case of supra-pubic lithotomy.

At Richmond, in 1881, Dr. Jacobi presided as Chairman and Dr. T. M. Rotch was made Secretary. The following papers were read: By Jacobi, Address on progress in the knowledge of the acute contagious diseases and infections; Relations between growth and disease, by H. P. Bowditch of Massachusetts; Middle ear disease in children in the acute exanthemata, by C. J. Blake of Massachusetts, and Thumb sucking, by D. H. Goodwillie of New York.

At St. Paul, 1882, William Lee of Maryland was chosen President in the absence of Dr. Busey, the Chairman, and E. C. Miller of Iowa, Secretary. N. S. Davis read a paper on the Efficient causes of serous diarrhea and cholera morbus in infancy and early childhood, and the best means of lessening the mortality therefrom; William Lee, on Treatment of rickets.

In 1883 the Journal appeared. The same year, owing to the absence of both chairman and secretary, C. W. Earle of Chicago was made Chairman and E. L. Bothby of Wisconsin, Secretary. Dr. Blount, the Chairman, assumed duty the second day. Papers were read on Unity of membranous croup and diphtheria, by Harris of Virginia; on Epidemic jaundice among children, by A. Y. P. Garnett of Washington, D. C.; on Surgical treatment of purulent pleuritic effusions in children, by W. H. Meyers of Indiana; A plea for pleasant medication and a more thorough study of infantile therapeutics, by C. W. Earle; on Dentition, by Good of Indiana; on Pediatric medication, by Casebeer of Indiana; on Infantile paralysis, by N. Teale of Indiana; on Diphtheria, its varieties and variations, by E. L. Boothby of Wisconsin. (Full names are not given because not published, the minutes of some Sections not being reported there was difficulty in finding these.)

In 1884 papers were read by S. S. Adams, on Incontinence of urine in children; Treatment of diphtheria, by J. W. Brown of New York; Septic jaundice of childhood, by M. P. Hatfield of Illinois; Feeding of school children, by L. W. Atlee of Philadelphia.

1885.—Repeated doses of castor oil in skin diseases of children, by L. D. Bulkley, New York.

1886.—Address by W. D. Haggard of Tennessee; Treatment of diphtheria, by D. L. Miller of Chicago; Why diseases of children should be made a special study, by Mary H. Thompson of Chicago.

1887.—Diarrhea infantum and allied diseases, by C. W. Jones of Chicago; Causes and treatment of entero-colitis in infants, by S. B. Sperry of Wisconsin; Infant feeding, by L. D. Bulkley of New York; Treatment of malarial fever in the infant and young child, by W. B. Lawrence of Arkansas; Congenital phimosis, by W. S. Stewart, of Philadelphia; Diphtheria, by H. L. Getz of Iowa; Eczema, by J. V. Shoemaker of Philadelphia.

1888.—The infant food problem, by W. B. Atkinson of Philadelphia; Intubation, by F. E. Waxham, of Denver; Infant feeding, by C. W. Earle of Chicago; Chorea, by G. W. Jones of Danville, Ill.; Is membraneous croup and diphtheria identical, by I. N. Love of St. Louis; Hepatic incompetence in children, by M. P. Hatfield of Chicago; Management of fevers in children, by J. A. Larrabee, of Louisville, Ky.

1889.—Scarlet fever, by C. R. Early of Pennsylvania; A penal rule of our common schools and some of its effects, by D. S. Booth of Sparta, Ill.; One year of acetanilid in pediatric practice, by I. N. Love of St. Louis; Physical education in children, by A. H. B. Leuf of Philadelphia.

1890.—A plea for operative interference in peritonitis with reference to its obscure origin in children, G. F. Lydston of Chicago; Antipyrin in children, by S. H. Desson of New York; Significance of high temperature in children, by W. A. Stowall of New York; Croup and diphtheria, by W. P. Watson of New Jersey, chosen Chairman, and W. R. Hare of Pennsylvania; Croup, by C. R. Earley of Ridgway, Pa.; Commercial milk sugar in infant feeding, by E. F. Brush of Mt. Vernon, N. Y.; Acute rheumatism in children, by S. F. Parsons of Boston; Value of atropin in enuresis, by R. B. James of New York; Further observations on foot and mouth disease in its relation to scarlatina as a prophylactic, by J. W. Stickler of Orange, N. J.; Alcoholic heredity in diseases of children, by T. D. Crothers of Connecticut; Feeding the young, by O. H. Phelps of Blocksbury. Cal.

1891.—Four hundred cases of intubation, by F. E. Waxham of Chicago; Acute bronchitis in children, by C. L. Dodge of Kingston, N. Y.; Relation of food to scorbutus in children, by E. F. Brush of Mt. Vernon, N. Y.; Acute meningitis and treatment, by G. H. Higly of Pennsylvania; Ought infants to be washed directly after birth, by F. S. Parsons of Northampton, Mass.; Eczema infantile, by D. M Ricketts of Cincinnati; Herpetic eruptions of the mouth and pharynx in children, by S. H. Dessau of New York.

1892.—Morbid proclivities and retrogressive tendencies in the offspring of mullatoes, by W. A. Dixon of Ripley. Ohio; Contagion of scarlet fever, by E. F. Brush of Mt. Vernon, N. Y.

1893.—Diphtheria, by F. E. Waxham of Denver, Colo.; Prevention of diphtheria, by J. Lewis Smith of New York; Recent advances in pediatrics, by C. G. Jennings of Detroit, Mich.; Isolated cases of diphtheria, by W. A. Dixon of Ripley, Ohio; treating cases of diphtheria, by G. B. Dunmire of Philadelphia; Discussion. Pathogenesis of bronchitis in infants and children, by W. S. Christopher of Chicago; Pathology and symptomatology of acute bronchitis and broncho-pneumonia, by C. L. Dodge, Kingston, N. Y.; Some phases of broncho-pneumonia in children, by J. M. G. Carter of Waukegan, Ill.; Pneumonia pathology and symptomatology, by F. S. Churchill of Chicago; Therapeutics of bronchitis, by I. N. Love of St. Louis; Treatment of broncho-pneumonia in children, by F. S. Parsons, Northampton, Mass.; Therapeutics of croupous pneumonia, by J. A. Larrabee of Louisville, Ky.; Discussion on these. Hernia in children, by W. E. Wirt of Cleveland, Ohio; Phimosis—a plea for its early relief, by J. A. Hofheimer of New York; Importance of early effective elimination in the zymotic diseases of children, by J. A. Work of Elkhart, Ind.; Meningocele with case, by A. G. Sloan of Dexter, Iowa; Infantile hernia, by T. H. Manley of New York; Treatment of chorea by [illegible] doses of quinin, by W. A. N. Dorland and C. S. Potts; Statistics of intubation, etc., by F. E. Waxham; Primary syphilis and gonorrhea in children, by B. M. Ricketts of Cincinnati; Cholera infantum in malarial localities, by J. Schenck of Mt. Carmel, Ill.; Dentition and its diseases, by M. Thrasher of San Francisco, Cal.; Acute endocarditis in children, by G. N. Highly of Conshohocken, Pa.

1894.—Pediatrics as a specialty, by W. S. Christopher of Chicago; Pneumonia in children, by E. H. Small of Pittsburg, Pa.; Exophthalmos in infant of three months, by H. E. Garrison of Dixon, Ill.; Derangement of kidneys in lithemia of children, by J. M. G. Carter of Illinois; Eczema of children, by W. M. Bolton of New Harmony, Ind.; Causes of therapeutic uncertainty in children, by A. C. Cotton of Chicago.

1895.—Enteric fever in infancy, by W. B. Noyes of New York; Typhoid fever in children, by J. E. Woodbridge of Youngstown, Ohio; Discussion on same. Guaiacol in typhoid in children, by A. Koenig of Pittsburg, Pa.; Acute lacunar diphtheria, by H. Koplik of New York; Antitoxin in diphtheria, by L. Fischer of New York; Diphtheria and antitoxin, by A. C. White of New York; Diagnosis and treatment of false croup, by S. Loving of Columbus, Ohio; Discussion on these. Antiphthisin in tubercle of children, by E. Klebs of Asheville, N. C.; Discussion. Scorbutus in infancy, by I. N. Love; Infantile diarrhea, by Rosa Engelman of Chicago; Colitis in infancy and childhood, by E. Anderson of Rockville, Md.; Pseudo-membranous enteritis with lumbricoides, by I. M. Snow; Sulphate of magnesium in summer diarrhea of children, by S. Patterson of Pittsburg, Pa.; Discussion of these. Has tuberculous cow's milk causative influence in infancy, by F. S. Parsons; Causes of great mortality in infancy, by J. A. Work of Elkhart, Ind.; Heredity and its environments, by J. E. Rigg of Wilkinsburg, Pa.; Bromoform in pertussis, by P. J. Eaton of Pittsburg, Pa.; Double club feet and hands, by B. M. Ricketts of Cincinnati.

1896.—Chairman, A. C. Cotton of Chicago; Secretary, A. J. Work of Elkhart, Ind. Diagnosis of diseases of infants and children, by C. G. Slagle of Minneapolis, Minn.; Sepsis of the new born, by H. E. Tuley of Louisville, Ky.; Chorea, by H. Hatch of Quincy, Ill.; Functional dyspepsia of children, by J. M. G. Carter; Spinal injuries in infants, by J. P, Fiske of New York; Treatment of fractured shafts of bones in children, by T. H. Manley of New York; Epilepsy following injuries in children, by W. A. Dixon of Ohio; Petit mal in children, by L. F. Bishop of New York; Discussion. Use of the stomach and rectal tube in children, by W. J. Bell of Atlanta, Ga.; Infantile scorbutus, by A. H. Burr, of Chicago; discussion. Evolution of girls, by H. E. Harrison of Dixon, Ill.; High pressure in teaching public schools, by W. H. Short of LaGrange, Ind.: Rachitic chest deformities in twins, by W. J. Bell of Atlanta, Ga.; Circumcision not necessary in young children, by W. B. Parks, Atlanta, Ga.

OFFICERS FOR THE SECTION.

1883. Chairman, W. Lee, Baltimore, Md.; secretary, W. R. Tipton, Las Vegas, New Mexico.

1884. Chairman, J. H. Pope, Texas; secretary, S. S. Adams, District of Columbia.

1885. Chairman, W. D. Haggard, Nashville, Tenn.; secretary, W. B. Lawrence, Batesville.

1886. Chairman, DeLaskie Miller, Chicago; secretary, W. B. Lawrence.

1887. Chairman, F. E. Waxham, Illinois; secretary, W. B. Lawrence.

1888. Chairman, J. A. Larrabee, Louisville, Ky.; secretary, C. G. Jennings, Detroit.

1889. Chairman, I. N. Love, St. Louis; secretary, E. F. Brush, Mt. Vernon, N. Y.

1890. Chairman, W. P. Watson, Jersey City; secretary, W. R. Hare, Pennsylvania.

1891. Chairman, E. F. Brush; secretary, B. A. Waddington, Salem, N. J.

1892. Chairman, C. J. Jennings, Detroit; secretary, F. S. Parsons.

1893. Chairman, W. S. Christopher, Chicago; secretary, F. A. Churchill, Chicago.

1894. Chairman, E. H. Small, Pittsburg; secretary, G. N. Michel.

1895. Chairman. As above.

1896. Chairman, J. A. Larrabee, Louisville; secretary, H. E. Tuley, Louisville.

The wisdom of the establishment of the Section of Pediatrics in the AMERICAN MEDICAL ASSOCIATION needs no better demonstration than is furnished by this history. Many of the early contributors are now enumerated among the authorities upon diseases of children. The claim of pediatrics as an established specialty in medicine is based upon the essential difference in diseases having the same nomenclature in adult life. The growing organism presents anatomic and physiologic peculiarities, which not only increase susceptibility to the acknowledged etiologic factors of disease, but also influence the rapidity of pathologic changes. There has been no advance made in medicine within the last quarter of a century which has resulted in greater benefit to the human race than that made in pediatrics. A closer and more careful observation by men who have devoted their entire attention to this field has been extremely fruitful in bringing to light new diseases. Diseases which formerly were considered rare in infancy and childhood by a closer observation have been found to be of frequent occurrence. The time when a few lectures tacked on to the chair of obstetrics sufficed to fill the curriculum of requirements of medical colleges has passed away never to return. Pediatrics as a special branch with ample clinical instruction, is today obligatory in all reputable medical colleges. Certainly there is no specialty in medicine which requires more thought, keener observation and more patient study than pediatrics. The embarrassment of a traveler in not being conversant with the language of the country which he visits, is not more than that of the practitioner who invades the domain of the nursery without having mastered the unwritten language of its diseases. Here particularly do I desire to emphasize the importance of a closer study of the physiognomy of disease as written in unerring characters upon the face of infancy and childhood. A language when once learned and understood is far less misleading than the spoken language of adult life.

Slumbering embers of disease are suddenly fanned into a fierceness which threatens destruction, while on the other hand we are astonished by sudden and unexpected recoveries in apparently hopeless cases. Disorders of the digestive system are of frequent occurrence and are fraught with consequences to the growing organism far beyond their significance in adult life. For this reason severe and protracted illnesses in early childhood arrest development and affect the mental and physical welfare of manhood and womanhood. Strikes among workmen may be noted by observation of the structures upon which they were engaged. Faults in the Commissary Department of our Army in times of peace would be far less disastrous than to an army actively engaged in the field. Malnutrition, malassimilation, improper food and faulty hygiene may thus cripple the corpuscular elements engaged in phagocytic war and place the child beyond possibility of repair. It is, therefore, of the greatest importance that the diseases of early life should receive prompt attention. If such conditions are overlooked or not properly understood they will culminate in serious conditions in adult life. Nothing which concerns the child should be considered as trivial.

When the AMERICAN MEDICAL ASSOCIATION, whose semi-centennial anniversary we today commemorate, was organized, there was a scarcity of pediatric literature. Choice and reliable works were in demand. Such works are always in demand, but the paucity of medical literature can no longer be regretted. The multiplicity of irresponsible medical publications is to be deplored. We are beginning to realize the force of Solomon's words, "of making many books there is no end." We can also appreciate the saying of Josh Billings, "that it is perhaps better not to know so much as to know so much that ain't so." It would be well if a healthy censorship could be exercised over our periodical publications. It is oftentimes exceedingly refreshing as well as profitable, to lay down the "up to date journals" and pick up a volume of Bennett, Flint, Wood or musty old Watson, and recognize in these great thinkers of a past generation the foundation-stone of the edifice of which we are the topmost structure.

The conclusions which we would draw from such retrospection would be that "every new thing is not true and every true thing is not new." The ambition to write a book is only equaled by the young man in Dickens' "Bleak House." The attempt to master the periodic medical literature of today will as certainly result in a mental dyspepsia as would an attempt to digest the entire *menu* at the Hotel Walton.

During the past year some of the doubtful, or at least debatable questions in therapeutics have become established. Particularly is this true of blood serum therapy and diphtheria antitoxin. It will be remembered that this Section, at Atlanta, presented especial attraction by reason of the talent arrayed on either side of this question. It must be considered for the benefit of future medicine, that all innovation upon established practice and all new or theoretic therapeutics should meet with severe criticism and even violent opposition. Antitoxin has certainly been accorded a liberal share of patronage in this direction. There is probably no better established principle in therapeutics than that quinin cures malaria, nor in inoculation, that vaccination exterminates smallpox, but physicians of London and Paris would have thrown old John Talbot and his bitter tea into the Thames or Seine before he cured Louis XIV. of France, and Jenner would at one time have shared the same fate from the populace whom he saved. The credit of discoveries in medicine and surgery should not redound to those who have simply conceived the idea, but to those who by persistent trial have demonstrated the utility. Your Chairman has no hesitancy in expressing the opinion that the past year's experience has materially lessened the ranks of doubters, and while the extravagant and unreasonable expectations of the over-sanguine have not been wholly realized, antitoxin must now be placed in the required armamentum of the successful practitioner.

The study of bacteriology aided by the wonderful revelations of the microscope has established a new era in the practice of medicine. Etiology and pathology, the formerly intricate mazes, have become plainer pathways and lead us more directly to the effulgent light of truth. This comparatively new field of medical observation presents so many attractions and is in itself so fascinating a study to the student, that there is danger of neglect of semiology. The devotee of the laboratory finds that he is poorly fitted for bedside diagnosis. For this reason clinical medicine must go hand in hand with laboratory work. Special work in medicine and surgery has been an essential factor in the advancement of a conjectural art to an established science, but the practice of specialties should be the outgrowth of natural predilection based upon years of experience in general practice, and the assumption of specialties by inexperienced college graduates is much to be deprecated. Hippocrates' injunction to his students to view the body outstretched, by which was meant a trained observation, is still good teaching. Germicidal therapeutics is all well enough and oftentimes commendable, but there are other indications in the treatment of disease than the possible destruction of pathogenic microbes. Someone has very aptly put this question by saying that in swinging a club to kill microbes we may hit the patient also. The older we grow in the practice of medicine, the more we are impressed by the thought that most of the diseases, as well as the troubles and trials of life, are preventable. It is as natural for an honest doctor to become a philanthropist as it is for a minister of the gospel to become a Christian. Preventive medicine and private and public hygiene mark the progress of the age in which we live. Proph[illegible]is is better than cure. We are all prompted by a [illegible]mmon interest, which is not always appreciated by [illegible]ur patrons, to sacrifice the comforts of life and if needs be life itself gratuitously for the extermination of disease, an object which, if attained, would effectually ruin our vocation. I shall never forget the address of the senior Gross when he was President of this ASSOCIATION. Never did that grand old man appear to me so lovely as, when crowned with all the honors of earth, the surgeon laureate of the civilized world, standing in the twilight of a well-spent life when only the "sorrows of others cast their shadows over him," he pleaded long and earnestly for a purer, better manhood and for the eradication of that vile blot upon humanity, which has entailed upon man and innocent childhood two-thirds of all their sufferings. As pediatricians, we have a better opportunity of knowing the hereditary constitutional diseases and also of judging the so-called cures of diseases acquired by parents. The thought is indeed a sad one, that among the thousands of infants now resting in their cradles such a number will suffer from inherited syphilis, so many will end their lives in misery, so many will help to swell the number of helpless cripples in our asylums, so many will fill our jails and workhouses, while not a small proportion are doomed to fill a drunkard's grave. It is a sadder thought to think, as we are forced to do from statistics gathered in our large and populous cities, that succeeding generations shall reveal a still larger number equally doomed. The hope is father to the thought, that from this Section with its wisdom, in future years there may be evolved laws regulating matrimony which shall forever preclude the possibility of placing upon the charities of the world a helpless deformity. The older nations of Europe, depleted by vice, and among the nobility by consanguinity, are framing such laws. Notably in France, and I am informed that in our own country the legislature of Texas has this matter under advisement. It has been proposed to make syphilis, cancer, epilepsy, inebriacy and tuberculosis tenable grounds for restricting matrimony and obtaining divorce.

There is no age of either ancient or modern civilization that can boast of such magnificent and munificent charities as the age in which we live. Asylums for the afflicted and unfortunate abound in every part of our country, while hospitals, reformatories and sanitariums appear on every hand. The demand for such institutions is still increasing and is met by a liberal response. Now while these eleemosynary institutions will remain as enduring monuments to Christian civilization, it can not be doubted that they tend to promote the degeneracy of the race by making the survival of the unfittest a possibility, thus reversing the Darwinian law. Nevertheless, we have not the authority of the Areopagi of Greece, nor the regulations of Sparta, to destroy diseased and perverse offsprings.

While I believe that some law regulating matrimony would be followed by a race improvement which would show in a single century, such legislation as proposed in France and Texas would be followed by an increase in certain classes of criminals, while illegitimate offsprings would present no better physical status. I believe that there is only one way in which this momentous question can be met and that is by a higher moral education based upon the study of medicine. It is therefore incumbent upon this Section to be an educator of the public, and teach people the importance of having a care for the progeny of man. If ministers of the gospel were educated in medicine we would have less sermons upon the sins of the Israelites and more upon our own society vices. It seems strange and unaccountable that man should be the only animal in regard to whose progeny no care is exercised while cattle and hogs are considered fit subjects for State legislation. The study of physiology and hygiene should be made compulsory in all schools and in all grades of the schools. Let it be understood that "the greatest study of man is man."

RENAL SUPPURATION, CATARRHAL, SPECIFIC AND TRAUMATIC, AND THE VALUE OF MICRO-URANALYSIS OF THE URINARY SEDIMENT AS AN AID TO DEFINITE DIAGNOSIS OF IT.

Presented to the Section on Obstetrics and Diseases of Women, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY THOMAS H. MANLEY, M.D.

PROFESSOR OF SURGERY, NEW YORK SCHOOL OF CLINICAL MEDICINE.
NEW YORK.

A peculiar clinical experience during the past year, has led me to the investigation of a class of lesions commonly enough encountered by most practitioners with fair opportunities for observation; but certainly in a considerable proportion of cases they are not understood, nor their clinical manifestations correctly interpreted. I refer to kidney abscess or pyonephrosis; of late, also designated "surgical kidney," for the reason that it is supposed that the lesion admits of relief or cure only by surgical measures, which is only correct, however, in exceptional cases.

Much diversity of opinion has arisen, in consequence of the confusion of terms employed by different authors, in describing the various types of renal suppuration; and, on the other hand, by an attempt at an over-refinement and irrational differentiation of pathologic conditions.

Thus we will note, that one speaks of renal suppuration as pyonephritis, another as pyonephrosis, another as pyelitis, and another as pyelonephrosis.

With our present knowledge of the most common mode of advance of suppurative lesions, it would be well, at least for purposes of diagnosis, if they were reduced simply to three varieties in non-complicated cases: 1. Primary catarrhal pyelitis. 2. Interstitial renal suppurative abscess. 3. Perinephric suppuration—extrinsic.

Catarrh—nephritis, suppuration—This is the usual type of renal suppuration when infection or spread of diseased processes is from below—*ascending.*

In this class it becomes a simple matter to trace the origin of pathologic processes from their source; but in a considerable proportion of cases, the clinical manifestations point to the renal parenchyma itself as being the seat of primary changes.

Interstitial suppuration—parenchymatous.—This may undoubtedly result from a back-flow of the urine, renal calculi, or tubercular infection. In this form, we may have either *open* or *closed* suppuration. In the former the pus *foyers* drain directly into the urinary stream; while in the latter, it is pent up and infiltrates.

Perinephric abscess.—By this term is to be understood a purulent formation of renal origin, burrowing through the inner capsule and discharging into the loose fatty investment or the retroperitoneal tissues. Pus may appear in the urine in very small quantities here, or be entirely absent, as in certain instances of encapsulation or obstructive pyelonephrosis.

Local causes of renal suppuration.—1. Lithiasis, calculus impaction. 2. Trauma, contusion or laceration of renal substance.

Toward the middle of the present century, Laennec, by the simple application of the laws of acoustics in the studies of pulmonary maladies, irradiated the whole science of physical diagnosis as it is applied to the detection of intrathoracic diseases. To one who has made anything like a methodic study of modern renal diagnosis of suppurative lesions of the kidney, it seems remarkable after Laennec's discovery, how we should have groped in the dark for so long a period without utilizing the means within our reach for more precise elucidation in the diagnosis of renal suppuration.

It will be my purpose on the present occasion, while considering a few features of renal suppuration, to point out how we may determine its presence, its character and extent with more certainty than we can a similar pathologic state in any other internal organ of the body.

Verhaagen has made a clear and rational distinction between the diverse varieties of renal lesions, which are *medical* or *constitutional* and those which are chiefly *local* or *surgical;* the former depending on blood changes or toxic states and the latter mainly on local influences. This latter only, can be briefly considered here, from the standpoint, chiefly, of diagnosis.

It is now quite generally conceded that renal suppuration or pyonephrosis very often depend ultimately on an alkalin fermentation of the urine. This has been quite conclusively demonstrated by several distinguished investigators; notably by Van Gieghem, Fels and Ritter, Klebs, Lister, Lancereaux, Lepine, Roux, Krozius, Roosing, Escherisch, Moselle, Schmidt and Aschoff.

Delafield believes that pyelonephrosis most commonly affects both kidneys, that "far as he knows, all these patients die; that when it is once established there is no control of the disease." Weir is not disposed to accept this view, and cites Goodhart's Guy's Hospital reports. This author collected 270 cases of death from urinary disorders, of which 130 were surgical kidney. In 100 of these, there were strictures. There were forty-one cases of suppurating kidney. There were but three in which the disease was limited to one side. In twenty-seven there was prostatic hypertrophy; in fourteen cancer of the bladder. There were forty-four cases of stone; twenty-nine cases of cancer of the uterus. There were fifty-six paraplegic; in twenty-six of these suppuration was limited to one side. On an average there were 14.5 per cent. limited to infection on one side. Dickinson, in sixty-nine cases of death from suppuration of the kidney recorded in St. George's Hospital, found in nineteen, pre-existing stricture of the urethra; disease of the prostate in twelve; in the remainder, there was loss of the vesical power, calculus and cystitis. In his opinion, the liberation of free ammonia in urinary decomposition is the chief factor in the etiology of pyonephrosis.

According to Bazy's statistics, in about 20 per cent. of cases of suppurative kidney, the lesion is unilateral. In Hamil's experience tubercular kidney is commonly unilateral; but if bilateral it is always much more severe on one side than the other.

I have been unable to gather from the literature on "surgical kidney" during the past fifteen years, whether suppurative formations are more common in one sex than the other, or on the left side of the body than the right. Since my studies on this class of lesions commenced, I am, however, convinced that renal suppuration is an infirmity very much more common than is generally supposed.

It is highly probable that in quite a considerable number of cases of presumed unilateral lumbago or nephralgia, the underlying lesion consists of calculous or purulent impaction of the renal pelvis, or the ureter.

In the past, we have been led to overlook the exact pathology of many extensive local renal lesions, because of the absence of grave constitutional symptoms from urinary disturbances, unmindful of the fact that the sound or unaffected organ on one side undergoes compensatory enlargement and thus relieves the one involved by disease. Da Costa maintains, and no doubt with truth, that abscess almost never effects primarily but one kidney at the same time.

Extrinsic and intrinsic injury of the kidney as an element in the causation of renal abscess or ulceratio—Exclusive of pyemic [illegible] or the plugging the arterial branches by substances carried in the blood the most prolific cause of abscess or ulcer of the kidney is trauma, mechanical obstacles to the flow of urine, the presence of autogenous bodies in the cortical substance, or the effects of violence applied from without. Dr. Henry Morris, in speaking on this aspect of the question, says: "Abscess of the kidney is one of the varieties of suppurative disease of this organ Its consideration might appropriately find a place in connection with injuries of the kidney, as they are the most ordinary causes of renal abscess." Mayer, in *Virchow's Archives*, describes a case of abscess, following the thrombosis of the renal artery, after an injury. In these cases, he believes, the primary changes commence with a calculus plugging of the tubules, purulent formation consecutively setting in.

The advances of pathologic processes in the kidney after the external injury are precisely the reverse of what occurs when they proceed from diseased conditions lower down.

In the former, we first observe perinephritic hemorrhage and inflammation propagated through the capsules to the cortex, then pyonephrosis, later pyelitis, ureteritis and cystitis. Physical influences are here the dominant factor; in the latter, chemical changes and the extension of infective, putrid processes.

The significance and source of pus corpuscles in the male and female urine and their relation to suppurative kidney.—A morphologic and bacteriologic examination of the urine, constitutes one of the most valuable aids known to medical science, in the diagnosis of lesions along the urinary tract.

In the present state of our knowledge of the subject, it might be, perhaps, not strictly within the limits of exact truth, to allege, that by a microscopic examination of purulent urine we are always enabled to determine with definite and absolute certainty the exact or precise seat of the morbid process; nevertheless the fact is, that by its revelations alone, we may ore completely elucidate diagnosis than by all our ther resources combined.

In this connection it is well to remember, that a preliminary, systematic, subjective, general and local examination of the patient constitutes an adjunct of the highest importance, which, taken together with the morphologic analysis, should in every instance decide with precision the pathologic process. On this point, however singular it may seem, there is at present some divergence of opinion, for while the general consensus of views supports this position, there are some few highly respected authorities not in full accord with it, who deny, in fact, that we are able to decide on the source of urinary pus by any special characters it presents.

But let us see on what grounds their premises are based and hear from the other side. Da Costa says: "As to the exact seat of the formation of pus, its existence in the urine affords us no clue," and yet with singular inconsistency he adds, "to some extent, however, we can judge of this by the microscopic appearance of the corpuscles. . . . The sudden appearance of pus in the urine in large quantities points to the bursting of an abscess. An abundant deposit of pus in acid urine is chiefly found in pyelitis."

Thudicum goes little further than to call attention to the special qualities of pus corpuscles in the urine, as indicating whether they are from a tubercular abscess or ulcer.

Johnson has described peculiar pus-casts and epithelia thrown off in the urine by those who later, on autopsy, were found to have renal abscess. Purdy says that "pus in the urine may be derived either from the free mucous surface of the urinary tract, an ulcer, or from the tissue substances; and in such cases it is liable to be mixed with elements of its place or origin, which become of great diagnostic value."

Le Dentu regards the diagnosis of pyuria as often very difficult. Brodeur calls attention to the great help of urinary microscopy in these cases.

"Casts composed of pus corpuscles," says Hare, "are rarely seen, but if constantly present, may indicate multiple abscess of the kidney; and when masses of micrococci become grouped together in the tubules and are expelled in casts the significance of their discovery is, that septic infection of the kidney is present. They are seen in suppuration, renal inflammation and in pyelonephritis, in which the true renal tissues are involved by an extension of the disease."

Simon, one of our latest and most advanced authors on this subject, declares that "a marked increase of leucocytes in the urine must always be regarded as indicating the existence of disease somewhere in the course of the urinary tract, except in females, when their presence may be owing to an admixture of leucorrheal discharges; in the latter the pus will be mixed with the pavement vaginal epithelia." This author declares that, "from a clinical standpoint it is of the greatest importance to establish the source of pus in every case of pyuria," and he adds, "a careful examination of the epithelial elements in the urine will be of great value and should never be neglected."

Bizzozero lays it down as a law, that in nephritis the number of pus corpuscles present stand in a direct relation to the intensity and acute character of the morbid process.

Roberts admits that, "in the first stage of pyuria the presence of characteristic epithelia generally sufficiently indicates the nature of the disease, but in advanced cases this valuable sign is not available." Newman is in accord with this view and claims that as new epithelia in the renal tubules, when shed, are small, imperfectly developed they can not be distinguished from pus corpuscles.

Musser says: "Urine containing much pus is slightly albuminous, but pus cells are found frequently in the urine which gives no albuminous reaction." This author makes the rather ambiguous statement in this connection, that it can not be decided from "a microscopic examination whether a cell is a pus corpuscle, a mucous corpuscle, a white blood cell or an inflammatory leucocyte."

Tyson practically discards uranalysis as an aid to localizing pyuria. Guyon is of the opinion that the presence of hyaline cylinders and various epithelia may, with pus, serve to decide its origin, but their absence by no means is negative of renal suppuration. Ralfe concedes that in the early stages of pyuria it is possible by a microscopic examination to determine its source.

From the foregoing we may gather: 1. That all investigators agree that the presence of pus in the urine, in considerable quantities, is always an index of serious or severe inflammatory action along some part of the uropoietic tract, when we eliminate genital admixture in the female. 2. There is a quite general accord of opinion on our ability to distinguish urethral from vesical suppuration, and recognize renal implication in the purulent deposits of early acute renal suppuration. 3. Many, especially medical authorities, are not yet prepared to admit that epithelial admixture in purulent deposits of the urine enables us to determine with certainty the precise source of leucocytosis in all cases. 4. A large and ever-growing number of observers, thoroughly trained in morphologic uranalysis, are emphatic and positive that the epithelial casts and parenchymatous elements thrown off in pyuria, taken in connection with other diagnostic aids, will invariably and with absolute certainty establish the source of pus production.

In America, my late master, the lamented eminent anatomist and pathologist of New York, Dr. Carl Heitzman, taught in his laboratory that the trained microscopist could not be deceived as to the exact seat of pyuria by a morphologic examination. This, he taught for more than fifteen years before his death. But, he was one of those whose modesty was only equaled by his profound erudition and great breadth of scientific achievement. In the current medical press he wrote little or nothing; but now that he has passed from among us, his great work on urinary morphology is making its impress felt wherever medicine is cultivated as a science.

It is my own conviction now, after some years of study on the subject, that the main reason why we are skeptic of the findings of urinary morphology, is because many who have had some general knowledge of the employment of the microscope in normal and pathologic histology believe themselves amply equipped to examine urine. The result, of course, is a lamentable failure, as, through want of a long technical training and opportunities under a skilled and experienced master, they are utterly incompetent to interpret the multiplicity of phenomena revealed by diseased urine.

In the present instance it will be my purpose to very briefly and incompletely call attention to the infinite value of the study of the morphologic elements of the urine in *renal* pyuria alone, as space will not permit a consideration *in extenso* of vesical or urethral, in connection with other diagnostic auxiliaries. Many writers and pathologists, it appears, in their efforts to divide the various types of kidney suppuration on an anatomic basis, instead of elucidating the subject, have greatly confused it. For example, an effort has been made to demonstrate such a lesion *per se* as pyelitis, renal abscess and pyonephrosis. But, let us take for example an impacted calculus in a renal tubule, and what do we have? 1. A distension of the tubules with epithelial erosion and leucocytosis—an *abscess formation.* 2. This impacted infarct is pressed into the mucous membrane of the renal pelvis, when we have *pyelitis.* 3. *The inspissated pus, detritus* or calculus, block up the ureter and widely distend the pelvis of the kidney, when we have *pyonephrosis.*

We might follow the course of this suppurative lesion further, and find, quite invariably, a ureteritis and cystitis.

The pathologic mutations are quite identical in infective lesions, though somewhat reversed or modified. My experience and training have taught me that with facilities now at our command we are enabled to determine with certainty the presence or absence of renal suppuration, or ulceration of the kidney as applied in its broad sense; but to differentiate an interstitial abscess from a pyelitis or a pyonephrosis, is as yet an impossibility. It will be noted that my observations here are restricted to the diagnosis only of the lesions which are entirely of a local character.

Before pursuing further, at present, the discussion of the morphologic elements of the urine, in surgical kidney, it may be well to turn aside briefly to consider some of the more pronounced subjective and rational signs attending renal suppuration.

Pyonephrosis without pyuria.—Four years ago, in a postmortem examination on a man who succumbed after an operation for gangrenous hernia, I came upon a greatly enlarged kidney on the right side. Its capsule was densely adherent to the adjacent parts and was unavoidably ruptured in its detachment, when an enormous quantity of pus with urine escaped into the abdomen. Nothing but a thin shell of cortical substance remained. Yet, in this instance, before operation this patient was closely questioned by me as to previous disease or infirmity of any description, when he denied ever having any other trouble than his hernia. I might add that the urine passed and examined after his admission to the hospital showed negative evidence of either sugar or albumin. No microscopic examination of it was made.

General symptoms and course.—The statements of many authors are certainly most misleading and erroneous with respect to the duration and symptomatology of suppuration within the kidney; some declaring with Delafield that it is progressively destructive, and others that its evolution is always attended with the most pronounced constitutional disturbances; while the fact is, that there is no more reason why we should not, and do not, as often secure a cure of a renal abscess, when it is uncomplicated, than we should of one of the lungs; and while, in some few individuals, surgery alone can save life and relieve the sufferings of the afflicted, there are others whose general health is almost never seriously menaced, and they continue undisturbed at their usual occupations. In my own cases the degree of suffering and invalidism was altogether greater in the females than in the males. Tuberculous infection was more common with them, while nephralgia or pyonephrosis from calculus was often met with in men. With two exceptions, every single case of unequivocal remittent pyonephrosis in the female ever coming under my care succumbed, while no case in the male, seen by me, has yet passed away from the effects of this lesion.

As to the acute or chronic course of pyelonephrosis, we have ample proof of cases which extended over years, as well as others which run a short course.

Dr. H. O. Walker of Detroit has reported a case in a young man who was a sufferer for nine years, and another, a female school teacher, who had renal abscess for four years, before prominent symptoms were manifest. In fact everything points to suppurative kidney generally being an exceedingly chronic disease, where there is a simple vent for the purulent deposits and the disease runs into the ulcerative stages. Much depends on the patient's age, general state of health and environment in the evolution of the disease.

There are certain individuals of vigorous health, with only one localized abscess of a kidney, who may pass through life without any symptoms of it, or at least until by some application of violence, exposure or indiscretion a fresh inflammation is set up; while there are others, in whom, from the beginning, indications of the lesion are quite clearly manifest. Of the former, Guyon records a case of a middle-aged man who for several months complained of occasional pains in the right side. His uranalysis was negative. He was later cut off by intestinal disease, when, on autopsy, it was found that the right kidney was the seat of a vast abscess.

Subjective symptoms.—The most common subjective symptom of renal lesion, accentuated by the onset of acute changes, is that generally known as renal colic, neuralgia of the kidney, or nephralgia, dependent on mechanical obstruction. The onset is usually sudden and the agony great. It does not appear that the renal parenchyma is richly endowed with sensory nerves; or at all events we have no evidence of stone or inspissated pus being present until it is forced out of the cortex and chokes up the pelvic outlet of the ureter. In these attacks the constitutional disturbances are extremely depressing until the pent-up decomposed urine, gravel, pus and detritus are washed away through the bladder and urethra. A patient, the subject of one attack, is quite certain of another if prophylactic measures are not instituted.

It is now well known that we may have suppurative degeneration of the kidney from ascending infection, chiefly of two varieties; one from gonorrheal infection, something very unusual, according to Senn, and in my own experience; and the other from the advance upward of those pyogenic bacteria, which are consecutive to the mechanical impediment to the passage of urine, by urethral stricture, prostatic hypertrophy, calculus, impaction or ureteral stenosis.

Tuberculosis is one of the most serious of the infective maladies that seize on the kidney. Bearing in mind then, the more ordinary causes of suppurative kidney, we will examine carefully for their indications as revealed through the subjective symptoms which belong to each, not omitting to inquire as to the possibility of trauma in the rôle of causation.

We will find in many chronic cases that the patient complains of pain *in the back;* always on one side more than the other, and extending down over the course of the ureter along the flank to the bladder. Polyuria, cystitis and vesical tenesmus are invariably present in advanced cases. In a few I have witnessed repeated attacks of neuralgia, involving the genitocrural, the iliohypogastric and sciatic nerves. But the symptoms may widely vary in renal suppuration, and in certain types we may have none of a pronounced character at all; certainly at times, not for long intervals. In certain individuals the agonizing cystic irritation coincident with pyonephrosis is almost constant; there is no let-up night or day; the hot ammoniacal, putrid urine coming down from the kidney has destroyed the vesical mucous membrane; the bladder is thickened and contracted, and no sooner has it drained off its burning contents than the patient is again seized with violent and protracted vesical tenesmus.

In tuberculous patients "pain in the side" low down with well marked evidence of cystitis, is an extremely suspicious symptom of renal abscess. Most women, the subjects of pyonephrosis, with few exceptions, will attribute all their symptoms to "womb disease," or to the "change of life," especially when they are about middle-age.

Another noteworthy symptom is an intermittent sensation of burning heat extending from the arch of the eighth rib down along the side into the hypogastrium. When septic toxemia is pronounced, rigors and sweats alternate.

These symptoms may be further divided, 1, into the constitutional and the local, and 2, into those which are constant or permanent, and 3, those which are intermittent or transient. The former are more frequently observed in connection with extensive interstitial pyemic infarctions, from secondary infections or in blenorrhagic metastases, so graphically described by Sée; the latter we observe especially in connection with calculous impaction or temporary plugging of the ureter. But we will occasionally meet with instances of pyuria of unequivocal renal origin, with very slight inconvenience to the patient.

Pain *in the side* or pain *in the back* is commonly borne by women; that of itself, except in extensive renal suppuration is of no distinctive value as a symptom. In some we will find that our patients complain of a dragging pain and a burning sensation over the affected organs. In most instances the patient is unable to lie on the same side, and when the body is at rest in the sitting or recumbent attitude the greatest degree of comfort is obtained.

In advanced cases the constitutional powers are seriously shattered, digestion is greatly enfeebled, the bowels are constipated and great bodily weakness is present. Along with this, a great change comes over our patient's whole being; broken down by long continued suffering, sleepless nights and want of food, they become melancholy, indifferent and irascible.

The most pronounced and prominent symptoms in many of these grave cases emanate from the bladder, cystic inflammation, ulceration and contraction. Probably at the outset when the urine is yet acid, its purulent admixture provokes little irritation, but as time progresses the purulent foyers in the kidney, or the putrid, ammoniacal, pent-up urine discharged into the bladder excites a septic inflammation, first destroying the superficial vesical epithelia, then the middle and deeper layers leading to an erosion and ulceration. In chronic cases inflammatory changes extend into the paravesical tissues, the vaginal, rectal, prostatic and seminal structures. The act of defecation or any severe straining produces a painful sensation over the hypogastrium, the rectum or perineum. The patient not only has polyuria and tenesmus, but usually has more or less urinary incontinence while on the feet. This is more pronounced in the female than in the male. Lumbago, sciatica and neuralgia down along the course of the anterior crural nerve and its divisions is a frequent symptom when renal tension is accenuated.

Physical examination; postural, surface and internal.—The state of the pulse or the degree of temperature are unreliable guides in a considerable number of pyurics. In some of my own cases the temperature was rather subnormal, while pus was draining away in great quantities. When the renal lesion is secondary to pulmonary tuberculosis, the thermal augmentation attends the hectic flushes. Colliquative and exhaustive perspiration is present in systemic invasion.

In all those about to be examined for renal suppuration it is important that the patients should be placed in different attitudes. The trunk should be well exposed below the mid-dorsal region.

In severe pyelonephrosis the kidney is enlarged and its volume and density increased, so that with few if any exceptions it will be found displaced downward and forward along the flank.

On palpation and deep pressure we will find on the affected side well-marked muscular rigidity, with a thickening of all the overlying tissues, and areas of more or less sensitiveness. Having taken advantage of gravity, as a primary step, the patient is first placed on the right side and then on the left, with or without a pillow under the lowermost side, as circumstances may require. Finally the patient is placed on the chest, with some central raised support under the abdomen in fat subjects, as recommended by Dr. Robert Morris.

By submitting patients to these tests and searching carefully for the diseased organ, in nearly every instance so far I have been able to detect a pyonephrosis without the clinching evidence of uranalysis. In some, its presence was so palpable as to render little more than surface examination necessary.

But when the right kidney is involved difficulties of great magnitude may arise, especially in the female; for this displaced, bulging mass of renal tissue may closely simulate perityphlitis, appendical abscess, pyosalpinx, abscess of the broad ligament, of Pott's disease of the spine, of localized malignant degeneration, etc. And I may add that without the microscope, in skilled hands, all our efforts to definitely and absolutely differentiate the one from the other, without mutilating the patient, would be utterly futile.

It is true that each of the above lesions pursuing a typical course is accompanied by a fairly uniform *ensemble* of symptoms; but the exceptions are only too numerous and we are often confronted by a most complex and embarrassing state of things.

The details of the physical examination of the subject have so multiplied of late years that it will be impossible in the present instance to but very briefly refer to a few of their more salient features as they apply to the detection and recognition of abscess or ulcer of the kidney. So late as twenty years ago but little was known of them and as a precise and definite means for the recognition of urinary lesions they constitute practically a new science.

They embrace an external and internal examination, an exploration of the tubular passages and a careful inspection of the urinary excretions. For obvious reasons, we must make a wide departure in our examination of the sexes.

When we suspect the kidney as the seat of suppurative changes, palpation, percussion and auscultation will serve us as valuable aids.

For a proper examination the patient should always be placed on a firm, flat surface. A strong table with a blanket over it answers better than any bed. In some, who have marked muscular spasm, an anesthetic might be desirable, but the renal lesion usually interdicts its use. It is always well to commence our examination with the patient lying flat on the back. In some the renal enlargement and tenderness may be readily detected in the prone position, but in others of stout build, or in whom the kidney remains fixed deeply in position, we must resort to other accessory expedients. We may flex the lower limbs on the trunk or raise the shoulders.

In all, with few exceptions, we will find a thickening, induration and spasm of the muscles in the lumbar and iliac regions of the side involved, along with tenderness over the course of the ureter and in the hypogastrium.

In woman we will easily determine varying degrees of renal displacement more definite and positive in some than in others; in all however more frequently than in men.

Firm renal pressure properly directed will quite invariably elicit definite indications of suppuration of the organ, especially when there is occlusion of the ureter and the pus cysts are large or multiple.

In order to proceed with success in our manipulations, bearing in mind the probability of renal displacement or unusual mobility, it will be well to first as definitely as possible determine the position of the diseased organ and its relation to others in its proximity. This having been effected, the palm of one hand is placed firmly over the left or right lateral lumbar region, while the other is pressed gently over the lax abdominal muscles in a direction approaching the other. Between the hands the kidney should engage. If a sensation of deep-seated pain or soreness is not at first elicited, then the pressure over the hypogastrium should be made in an intermittent manner—an up and down motion and with more force.

As a rule, in cases of renal suppuration, simultaneously or soon after pressure is applied the patient complains of pain along the ureter into the bladder.

Examination by the orifices or tubular passages.—This is conducted by two methods: 1. Digital examination *per rectum et vaginam.* 2. By reflected light, the cystoscope or ureteral catheters. For various reasons, except in special cases, a rectal examination will throw but little light on any lesions along the urinary tract, except when the prostate or bladder is involved, or in those wherein differential diagnosis is necessary. With the female maiden, however, as an avenue to the access to the pelvic organs, it is different.

The vagina of a multiparous woman will permit, generally, of such an examination as will enable us to determine the presence or absence of pelvic phlegmasia or tumors, although it is well to remember that these may coexist with renal suppuration. Endoscopic examination of the urethra and bladder is undoubtedly one of the greatest aids in the diagnosis of lesions involving these organs. Valentine of New York has demonstrated its positive value in the detection and study of lesions along any areas of the urethra and bladder, and in fact, in our time, no genito-urinary surgeon is regarded as at all properly equipped without the cystoscope and ureteral catheter. But its intelligent use requires special skill and extended experience; besides, it is almost unnecessary to add that in the presence of stricture, enlarged prostate or a tortuous canal, its employment is quite impossible.

Willy Myer, and Kelly particularly, in America, have shown us the possibilities of ureteral catheterization in the male and female. Everyone concedes the practicability of introducing a ureteral catheter by way of the floor of the healthy female bladder in many, although not a few gynecologists claim that it is utterly impossible in a considerable number; in the patulous, partly stenosed or tortuous ureter. Skene admits that it does possess some value as a remedial agent, but denies its utility for general diagnostic purposes. It involves always a considerable urethral dilatation and more or less trauma of the sensitive vesical and ureteral mucous membrane.

It seems, therefore, quite inconceivable that the ureteral catheter can have anything other than a very limited application in the male subject; probably none at all in the presence of cystitis, or such organic changes in the bladder and ureter as have been recently so well described by Myles of Dublin.

Exploratory incisions.—Any procedure which involves a mutilation of the body, in the ascertainment of diagnosis, is a humiliating confession of failure. Except, indeed, in cases of very rare occurrence, presenting very grave and complex features, it is something of more than doubtful propriety; in fact, it should be ruled out.

The time is past when anyone should further impose on our credulity by informing us that "exploratory incisions opening into the abdominal cavity are harmless."

When, however, one is in doubt after having exhausted all other diagnostic methods known to science, then it may be justified, when we contemplate combining simultaneously therapeutic measures with diagnostic exploration.

(*To be continued.*)

ALCOHOL IN MODERN MEDICINE, OR ITS PRESENT POSITION AS A REMEDIAL AGENT IN THERAPEUTICS.

PRELIMINARY REPORT AND BRIEF SUMMARY OF A SPECIAL JOINT COMMITTEE OF THE AMERICAN MEDICAL TEMPERANCE ASSOCIATION AND THE AMERICAN ASSOCIATION FOR THE STUDY AND CURE OF INEBRIETY, FOR A SPECIAL STATISTIC REPORT OF THE PRACTICE AND OPINIONS OF AMERICAN PHYSICIANS ON THE USE OF ALCOHOL IN MEDICINE.

Presented to the Section on State Medicine, at the Forty eighth Annual Meeting of the American Medical Association held at Philadelphia, Pa., June 1-4, 1897.

BY ISAAC N. QUIMBY, M.D., CHAIRMAN.

JERSEY CITY, N. J.

The following questions soliciting answers from members of the medical profession of the United States were printed and distributed by a committee of physicians representing The American Association for the Study and Cure of Inebriety. The circular which explains these questions is herewith presented:

JERSEY CITY, N. J., March 1, 1897.

My Dear Dr. ——

We shall be pleased to have you write out your experience and views in answer to the enclosed questions and return to me at your earliest convenience.

We wish to obtain with some exactness the present status of the use of alcohol in medicine and the views of the leading medical men in this country.

The results of this inquiry will be presented at the June meeting of the AMERICAN MEDICAL ASSOCIATION at Philadelphia.

Thanking you in advance for your labor and assistance, I am, very truly yours. I. N. QUIMBY, Chairman.

T. D. CROTHERS, M.D.
F. H. KELLOGG, M.D. } Committee.
L. D. MASON, M.D.

Explanatory remarks.—Up to this time the answers to the fifteen questions give a summary of the opinions of one hundred and twenty medical men scattered more or less widely over the United States. The larger proportion of these are experienced and old practitioners, many having practiced fifteen, twenty-five and thirty years and averaging twenty years of varied and extensive medical experience; nine from forty to fifty and three from fifty-five to sixty years. It is but just to the committee to state that the question blanks were distributed without any knowledge of the possible outcome of such distribution and with a few exceptions none of the committee knew the views, on the questions submitted, of those to whom the blanks were sent; *so* that the replies to the fifteen questions may be inferred to be a fair representation of the position which alcohol holds as a drug in modern therapeutics, as far as these replies can attest to the fact. About six hundred of these questions were issued by the committee and 120 replies were received, the total contributing a valuable addition to the views of the profession today on the position of alcohol in modern therapeutics. The committee have endeavored to procure a candid opinion from all the physicians applied to and have therefore reported in full, and in the words of the writer his opinion *pro* or *contra*, so that fair conclusions may be drawn by those who may be interested from the statements given *verbatim* and not in the language or interpretation of the committee.

The answers will speak for themselves, but in order to call attention to some of the more salient points in the questions and in the answers to them the committee feel obliged to make a brief summary of the facts presented.

1. To what extent and under what circumstances do you use alcohol in your practice, either hospital, dispensary or private?

The term alcohol is used in a general sense so as to mean the drug itself, pure and simple or tinctures, malt and vinous or spirituous liquors containing a greater or less per cent. of alcohol. We infer from the answers that this fact was understood, at least in the majority of cases. To classify the replies to these questions we divide them into, 1, those who do not use alcohol in any form; 2, those who have used alcohol only as an *external application*; 3, those who have used alcohol to a limited extent and under certain conditions and restrictions and who were conservative in their views, and finally, 4, those who have used it freely and liberally "to any extent and under all circumstances when a diffusible stimulant was indicated." In these four classes we find two extremists; *non-users in any form* and those who use *alcohol freely in their practice.* A careful study of the question blanks shows that the third class, those who use alcohol to a limited extent—the conservative class—are in a large majority. But if we carefully study the answers of this class it will be noted that the use of alcohol as a remedy is limited in its application to a certain type of diseases and that its use is decidedly restricted as compared with its use twenty-five or thirty years ago. It is certainly not the "universal panacea" for "all the ills that flesh is heir to" as it was then, and its use by those who advocated its advantages is restricted to a certain class of cases—we refer to the replies. The testimony on this point is quite conclusive.

In the Matteawan State Hospital, with an average of 590 inmates, for twelve months the consumption was sixty gallons of whisky and thirty gallons of wine. In one hospital 110 patients (mostly surgical) averaging sixteen days each, used less than one-half a gallon of brandy (Galloway, Chicago). In the Portland Sanitarium, Oregon, it is not used at all. It seems to be very seldom used in dispensary practice. In hospitals it is used in emergency cases, shock, before or after operations, in adynamic state of fevers and pulmonary diseases. Although the replies are not very full on this point we may venture to remark that the "institutional use" of alcohol as a remedy is more limited than formerly. It is well to note that not only the nature of the disease, but locality, climate, character of the population, tenement or otherwise, season of the year, occupation and habits of the people, nationality of the person and other conditions, severally seem to have an influence in determining whether or not the physician shall use alcohol in this or that particular case.

2. To what extent and under what circumstances, according to your observation, is alcohol used in hospital, dispensary or private practice of physicians of your acquaintance?

While the answers as to the personal use of alcohol in the respective practices of those replying are in favor of its gradual disuse or limited use, the answers to Question 2 are, in many instances, unsatisfactory, where the question is answered; but on the whole the testimony is in favor of the more guarded and scientific as well as limited use of alcohol as a remedy. But the fact remains that a large proportion of physicians use alcohol in some form as a remedy in their practice, and some of these *do not* guard its administration with the same restrictions and safeguards as they do other drugs. We claim that alcohol should be given with the precautionary measures that surround the administration of other narcotic-poisons, opium and its alkaloids, cocain, etc., and to which the patient is in danger of becoming habituated. (See examples of answers.)

Examples of answers to Question 2.—As a diffusible stimulant and in adynamic stages of acute diseases; in surgical shock, in threatened collapse from any cause; in delirium tremens to control fibrillary spasms; after severe surgical operations; as officinal tinctures and externally; in tedious convalescence after fever or debility from other causes; fainting, collapse, shock, anesthesia narcosis; temporary stimulant only, as in shock; sometimes in intestinal disease, as a substitute for food; in all cases of sepsis; all diseases of a rapidly acute asthenic type; in diphtheria, do not use it in chronic diseases of the young and middle aged; large experience in chronic pulmonary disease, in the majority of cases California red wine preferred; in prostration stage of typhoid and pneumonia, never as a routine remedy; low fevers, debility and exhaustion; in all cases requiring prompt stimulation; sometimes for its anesthetic effect in hopeless cases, adynamic stage of typhoid fever or pneumonia or diphtheria, and old persons; phthisis and pulmonary edema, pneumonia; in surgical work do not use one-half pint of whisky a year, had 278 operations; heart stimulant, old persons as tonic and stimulant; with ammonia carbonates in pneumonia, and in malted milk in malarial and typhoid fevers; acute infectious disease; exhausting chronic conditions; snake bite (as antidote); malignant diphtheria; bronchial catarrh of the aged; as force food, hepatic functional stimulant, as a vasomotor sedative; in shock, otherwise very little internally, and as an antiseptic in gargles, mouth washes and lotions; in pneumonia and typhoid fever; when the case is hopeless and life can not last long, for its anodyne and soporific effect, euthanasia; typhoid fever and convalescence; as an emergency stimulant; as an antiseptic (never as a stimulant), rattlesnake bite, typhoid and typhomalarial fevers; shock, convalescence from protracted and wasting disease; old inebriates (alcoholic habitués), nursing mothers (galactagogue), acute asthenic diseases of children; in shock and before chloroform anesthesia; low type of fevers.

3. What drugs in your opinion, may be advantageously or satisfactorily substituted for alcohol in medical practice, and what, in your opinion, is the comparative value of alcohol and of strychnin, used by the mouth or hypodermically?

This is a very important, as well as interesting question, asked with a view to determining the favorite heart tonic of practitioners, as well as their views concerning the same as a substitute for alcohol, particularly with reference to strychnin. The answers will therefore bear close scrutiny and may be studied with advantage as they are full of suggestion and practical value. With some, strychnin "is of greater value and more certain in results" than alcohol and preferable to it; with others it can not take the place of alcohol and acts in a manner quite different from it. Although the majority of the answers acknowledge the usefulness of strychnin in cases of alcoholism, it is *par excellence* the heart tonic and antidotal to the evil effects of alcohol, as well as a substitute for it. All the answers will well repay a careful study as to the relative merits of alcohol and the various nerve and heart tonics, strychnin, nitroglycerin, etc., and the respective conditions in which each is more especially useful as compared with others.

4. Have you ever studied the treatment of diseases of a similar character *with and without alcohol*, and what did the record of cases so treated demonstrate? Was the testimony in favor of the alcoholic or non-alcoholic method of treatment? Can you cite cases?

Another question of great interest and one that has divided the profession at home and abroad so far that non-alcoholic treatment of cases is not uncommon, and special hospitals have been established in which alcohol is not used as a remedy. The reports are not as full as we might desire. One physician reports a mortality of 7 per cent. in typhoid fever with alcohol, 1 per cent. without alcohol. He states, "I have treated 283 cases of typhoid without alcohol and lost only three cases, and these were marked cases" (Bleighton). Another reports, "Yes, surgical cases and I am inclined to the non-alcoholic treatment" (Bovie, D. C.) Another does not recognize an alcoholic or non-alcoholic method of treatment. Another, "The advantage of alcohol in chronic pulmonary conditions." Another, "I have made a special study of 100 cases of typhoid without alcohol and 100 with, and the results are greatly in favor of treatment without alcohol."

With regard to the alcoholic or non-alcoholic treatment of diseases, excluding the replies of those who are doubtful or have formed no definite opinion on either method of treatment, the profession seems to be nearly equally divided with the preponderance in favor of the non-alcoholic method. Thus, twenty-four expressed decided preference for the use of alcohol in the treatment of certain specified conditions of disease, thirty-eight markedly pronounced in favor of the non-alcoholic method, and the balance had formed no definite opinion, or were not positively in favor of either method, so that we may state from the records that the answers decidedly favor, when positively given, the non-alcoholic method of treating disease. It should be also stated that when alcohol is used its advocates give specific and intelligent directions as to the diseases and conditions under which it is to be used, and we may state that a careful study of these diseases and conditions limits the sphere of alcohol as a remedy to certain diseases and certain definite stages of those diseases, and practically, therefore, condemns indiscriminate use and indefinite dosage as not only unscientific, but positively harmful.

The questions and replies in detail are appended and respectfully commended to the thoughtful.

5. What proportion of persons among the laity, according to your observations, make use of alcohol as a domestic remedy, and what form of alcoholic beverage is most commonly used?

An analysis of the answers to this question shows that the great majority, fully 90 per cent. of our families, keep alcohol in some form, either whisky or brandy, and resort to it as a domestic remedy for all slight or severe, real or imaginary ailments. A fact also brought out is the use of alcohol as whisky or brandy, for painful menstruation, and another fact the large consumption of alcoholic liquors in the shape of patent or proprietary medicines, medicated wines, malt extracts, tonics, tinctures, etc. The question arises how far the family physician is responsible in his relation to the family as medical adviser, for the almost universal use of alcohol in some form as a domestic remedy, and what is his duty in the premises, in pointing out the fact that alcohol is not a universal cure-all as it is supposed to be, and that it is often positively detrimental in its effects in diseased conditions.

6. To what extent, in your opinion, does the moderate but habitual daily use of alcoholic beverages produce disease?

As to the term "moderate" as applied to the use of spirituous liquors, there is great difference of opinion. We think the term is an unfortunate one, indefinite, unsatisfactory, but we have used it in a conventional way, and as it is generally used, leaving to each one questioned the privilege of interpreting the term according to his own views and experience. The "habitual daily use" is a phrase more definite and ought to be answered in a satisfactory manner.

In the opinion of some, "moderation" means four ounces of whisky, or a glass or two, or two or three drinks daily, or two or three ounces of spirits daily, or one-half ounce distilled liquor well diluted; or three glasses of malt liquor a day can do no harm, except whisky; one writes, no harm, except in gout; another, no harm after meals, properly diluted in moderation. No harm, beneficial after middle life, in moderation, etc. What constitutes moderation in the opinion of this section? Those opposed to habitual daily use of alcoholic beverages in moderation, or at all in any quantity, in brief assert that it lowers vitality and resistance to disease, increases mortality and shortens life expectancy; that its use is prejudicial to physical, mental and moral tone, and so, indirectly, fosters habits of life that lead to injury and disease; that moderate use of alcoholic stimulants leads to excessive use or, as one puts it quaintly, "Pigs grow to hogs, and hogs root up the garden." It creates an artificial desire and, as we have said, paralyzes the moral sense and so leads to disease, *i. e.*, leads to gout and forms of sclerosis, develops predisposition to disease: where diathesis exists, prefers to give alcohol —to a non-alcoholic—to get definite results; moderate use of alcohol produces a bias in favor of disease, tends to fatty degeneration of tissue, etc.

The majority are seemingly opposed to the so-called moderate habitual daily use of alcoholic beverages and believe that such use directly or indirectly produces disease.

7. In your observation what are the prevalent forms of disease among those who habitually use alcoholic beverages in moderation, and are they less or more susceptible to disease than total abstainers, or is the relative frequency the same in both classes of persons?

Moderation means more than is consistent with good health; on an average two ounces of whisky; one pint of beer; here are a few of the replies in a condensed form: In cardiac, nephritic, hepatic disorders, and subsequent fatty degeneration; gastric disorders; neurasthenia, insanity, nephritis, hepatic cardiac disease, obesity; susceptibility to disease, rheumatism; dyspepsia; Bright's disease; susceptibility to disease; diseases of stomach, liver and kidneys; susceptibility to disease, gastric, renal, hepatic; rheumatism, gout and mania; susceptibility to disease; "alcoholic pneumonia," with grave prognosis; users more susceptible to disease than total abstainers; do not believe that four ounces daily in adults will produce disease, or that moderate drinkers are susceptible to disease; the relative frequency of disease is the same in moderate drinkers and abstainers; the term "moderate" is relative, and moderate drinkers as a rule become excessive drinkers and so disease results; habitual beer drinkers are especially short lived.

It is interesting to note in consulting the various answers that the majority, however they may differ as to the moderate habitual use of alcoholic liquors being a factor in directly producing disease, agree that persons so using alcohol have a lower power of resistance to disease, and are more susceptible to disease than total abstainers, which is an important fact brought out and substantiated by these statistics.

8. Do you think the use of alcohol in any form as a domestic remedy is increasing or decreasing, or have other narcotics been substituted?

About 50 per cent. of the answers assert that the use of alcohol as a domestic remedy is on the decrease, and about half of these answers state that other narcotics have been substituted, notably the coal tar derivatives, phenacetin, antifebrin, etc. About 10 or 12 per cent. assert that the use of alcohol is increasing as a domestic remedy. One or two replies from southern physicians attribute this to the lax administration of the liquor law in their respective States. About 6 or 8 per cent. believe that the use of both alcohol and narcotics is on the increase. A small percentage deny that the use of either is on the increase or decrease, but about stationary. Other views are also given, namely, that the lighter forms of wine and beer are substituting—distilled liquors—and that the higher and intelligent classes of society are becoming more temperate and that *hard times* favor decreasing use of liquors, wines, etc. The balance, probably 25 or 30 per cent., do not answer this question.

9. What proportion of the laity, according to your observation, make use of alcohol as a beverage?

About one-third do not answer this question, or do so indefinitely. From the replies of those who do answer, about two-thirds of the whole number, the following conclusions are drawn:

(1) That from 50 to 60 per cent. of adult males use malt or spiritous liquor as a beverage.

(2) That 10 per cent. use distilled liquors and 90 per cent. malt.

(3) That the proportion of males to females is as 5 to 1—the tables on this point are not very definite or full.

(4) Its use is less prevalent in rural districts and more prevalent in large cities, especially in seaboard and manufacturing towns.

(5) The number of habitual drinkers to occasional drinkers is as 1 to 5.

(6) The use of wine, spirits or beer is more common among foreign born than native population.

(7) The environments, occupation, nativity, locality, sex, age, etc., all influence the use of alcohol as a beverage.

(8) Different States and localities show a marked difference; one states that "in Kentucky *everybody* drinks whisky." "In a prohibition town in Arkansas, only 2 per cent. use alcoholic stimulants as a beverage; this is a prohibition town, 'and prohibition prohibits.'"

10. For what length of time have you given especial consideration to the effects of alcohol as a medicine?

Those who had observed it less than ten years, 9; from ten to fifteen years, 24; from fifteen to twenty years, 3; from twenty to twenty-five years, 14; from twenty-five to thirty years, 12; from thirty to thirty-five years, 2; from thirty-five to forty years, 1; from forty to forty-five years, 6; from fifty-five to sixty years, 3; in all, 74. No answer was given by the balance.

Of the seventy-four recorded, over 50 per cent. had given their entire professional life to the study of the problems involved in these tables, such professional experiences extending over twenty years in all cases. The inference must be that the testimony here submitted is given by professional men and after long and practical experience.

11. To what extent, in your opinion, does the medicinal use of alcohol encourage, either directly or indirectly, the habitual use of alcohol by the laity, and, as a consequence, inebriety?

We may classify the answers as follows: Those who believe the medicinal use of alcohol *does not* in any way lead to its habitual use and as a consequence, inebriety. Some thirty so affirm, as follows: Properly used; in acute disease; properly used; no, promiscuously, yes; libel on the profession; excuse (unwarranted) of inebriates; argument of extremists; properly used, no; patent medicines, etc., yes; regular prescription, no; "advice of physician" an excuse; not if by a temperate doctor; yes, if by a whisky-drinking doctor who gives it on *all* occasions, for *all* conditions, in *all* diseases; all drunkards are liars; statements not reliable; never after 50 years of age; yes, indiscriminately given; no, in cases of temperate people and children. Twenty-four say "yes, but to a very slight or moderate degree." Thirty-four say "yes, in some instances"; about one in fifteen, "principally patent medicines"; careless prescribing; verbal directions more or less indefinite; yes, in chronic, no, in acute cases; heredity; idiosyncrasy; one-half of 1 per cent.; especial tendency; four out of five; only six cases in thirty years; yes, great numbers; to a large extent in country practice, where the patient is his own physician or left to his own devices.

The consensus of opinion would be: 1. That the medical use of alcohol develops the habitual use and from this inebriety under certain conditions. 2. That the risk of such a result was much lessened if the patient was previously temperate and of good family history, over fifty years of age, and the case one of acute disease—also in the case of children. 3. If indiscriminately and carelessly given, especially in chronic diseases, history of heredity or peculiar idiosyncrasy, the patient continuing to use the remedy after the physician ceases to attend him and yet with the apparent sanction of the physician; under such conditions the habitual use of alcoholic liquors is established and in a certain proportion of cases results in inebriety.

12. When you prescrible alcoholic beverages as a medicine, do you specify the form, the quantity, the period, and especially the length of time in which it is to be used as a medicine? In your opinion, are not specific directions desirable and oftentimes important in the use of alcoholic beverages?

All answers are in the affirmative; a few of them specify kind, quantity and time; same care as with other medicines; explicitly; yes, emphatically, yes; absolutely so; important; yes, disguised with other tinctures; I do not give alcoholic stimulants, if I did I should prescribe alcohol (to secure definite dosage); limited period and specific directions.

From the testimony here given it would be in evidence that physicians as a rule do not prescribe alcoholic stimulants, carelessly or without restrictions. Our remarks apply to conscientious and intelligent practitioners and not to "intemperate doctors."

13. In your opinion, is the medicinal use of alcohol increasing or diminishing?

Fifty-six believed the medicinal use of alcohol (meaning thereby alcoholic and malt liquors, etc.) is decreasing; some assert that *legitimate* use only is decreasing, not the *illegitimate* use; also that much depends on the doctor of a particular locality; it is given with more discrimination; malt extracts and light wines are more used; various wines are drugged and disguised and sold by the wholesale drug houses as tonics, etc. About a dozen believe the use of alcohol is neither on the increase nor decrease. Thirteen believe its use is increasing, not probably in its purer forms, or as stated, in "medicinal wines," malt extracts, tonics, tinctures and alcoholic preparations of various kinds. The rest give no data. The preponderance of opinion seems that there is a decrease in the use of alcohol as a remedy and that when employed it is with more limit and discrimination than formerly.

14. What form of alcoholic beverage do you generally prescribe—distilled or malt liquors, or the various wines—and under what conditions and for what purposes?

About one-third do not prescribe alcohol in any form, under any conditions.

The remaining two-thirds use distilled liquors in some form, as a diffusible stimulant or "force food"; whisky seems to be the favorite, brandy occasionally, and one or two recommended *pure alcohol*—diluted with water—as susceptible of more definite dosage and results; malt liquors, as food in certain wasting diseases and as a bitter tonic; some prefer "malt extracts"; one physician, *old Jamaica rum* to whisky or brandy. The majority never prescribe alcohol in any form as a *beverage* and limit its use to the acute stages of disease, and others to the period of convalescence. Exception made in cases of aged persons for its continued use as wine, red wine preferred by some, and California wine preferred. The "ærated" wines, champagne, etc., in certain conditions. Some never give it to intemperate persons and to alcoholic habitués, only in disease.

The general opinion favors alcohol in some form, under certain conditions *pro re nata*, but condemn alcohol as a beverage and its use in chronic diseases, except in exceptional cases, and deprecate its continual indiscriminate or unscientific use

15. In your opinion, [illegible] tre[illegible]t of dise[illegible] are the lighter forms [illegible] b[illegible] the v[illegible] forms of alcoholic [illegible] [illegible]rce of alcohol is great[illegible]

About 43 per cent, there is no change; about 35 per cent. think that there is; about 20 per. cent. do not answer or are indefinite; about 2 per cent. do not use wine medicinally. One of the latter class does not use it because a pleasing, and therefore dangerous, form, especially for the young, and apt to be used indefinitely; uses whisky and brandy *pro re nata* only, and not as a tonic. Another physician regards wine as absolutely worthless from a scientific and medical standpoint. Another states, other things being equal; a larger quantity of wine is given to produce certain results; when a smaller quantity of distilled liquors would do, the same quantity of alcohol is given, although the form, etc., in which it is given is changed.

In closing I wish to heartily thank those physicians who have so kindly responded to our committee's request, thus aiding us materially in our attempt to open up a comparatively unexplored field of inquiry into the power of alcohol to injure the human tissue and retard cell growth and development.

We are just at the beginning of a new era along the line of scientific investigation and many physicians who now prescribe and advocate the use of alcohol and its derivatives will look back with astonishment in the early dawn of the new century at the erroneous position they had occupied on this important and far-reaching question.

It is to be regretted, however, that there is such a diversity and divergence of opinion in reference to a substance (alcohol) which is in such universal use, and with such seductive and destructive tendency.

It is also to be regretted, judging from a number of answers received, that many physicians are in the habit of prescribing alcohol and strychnin (remedies diametrically opposed in their action) as a stimulant or heart tonic.

The use in combination of two powerful drugs, so diverse and antagonistic in their action as alcohol and strychnin, is quite unscientific.

Now it is clearly demonstated that alcohol acts on the brain mainly and nervous system, in fact is a brain poisoner, perverting and deranging the physical, mental and moral faculties, while strychnin is a *true* tonic and acts mainly upon the spinal cord, with none of the destructive tendencies of alcohol.

You will scarcely find a physiologic opponent of the non-alcoholics in medicine who does not make a handle of the word stimulant, while advocating the use of intoxicating drinks Every one acquainted with the nature of life is aware, that without stimulants, life is impossible for any length of time. Food, water, air, light, heat, etc., are not only stimulants of life, but habitual, healthy and absolutely necessary stimulants of combustion. The lash of the whip, the prick of the needle or bayonet or the sting of the bee, etc., are also stimulants, but they are neither pleasant, necessary or wholesome. So alcohol in this sense is a stimulant.

Therefore the opponents of non-alcoholics argue, though it may not be necessary, it is hence a beneficial auxiliary of life. Disregarding and concealing the fact that alcohol is not only a stimulating irritant, but a corrugator and paralyzer of the living tissue, as well as a narcotic poison. The excitement of all natural stimulants is not necessarily followed by a corresponding depression, but it is the inevitable result of alcohol and all other narcotic stimulants that they are followed by depression, more than equal to the excitement produced, so that a person using narcotic stimulants is more depressed than ever and therefore is more inclined to repeat and increase the dose. This is the unsuspected pitfall into which thousands of the unwary plunge.

But amid all the confusion and doubt and darkness and superstition, it is gratifying to know that all physicians and scientists, physiologists and chemists, who have recently made and are making scientific investigations, with the modern instruments of presision, in reference to the action of alcohol on living growing tissue have arrived at about the same conclusion as is proven by the recent experiments in the physiology of alcohol by Prof. F. Hodge of Clark University, etc., *i. e.*, that it retards, perverts and is destructive, either in large or small doses, to normal cell growth and development.

Allow me to diverge from the strictly scientific aspect of the question. It should concern the medical profession to know that juvenile crime is increasing, both in this country and in Europe. The juvenile criminals are undersized and sickly, and many have a feeble intellect, bluntness of feeling or unstable will. One would not have to draw much upon his imagination to attribute or connect the cause for this increase and degeneration to the increasing use by the parents of alcohol and other narcotics. The operation of heredity has fastened these defects upon them, as a rule, so that they must be regarded as belonging to a decadent class.

This is a significant fact which the medical profession or the public can not safely disregard.

ALCOHOL VERSUS ANIMAL POISON.

Read before the American Medical Temperance Association, in the Section on State Medicine at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY CHAS. H. SHEPARD, M.D.

BROOKLYN, N. Y.

Animal poison is by no means uncommon, and so quick and mysterious is its action that a prompt remedy is a vital necessity. There is good reason to believe that the numerous remedies that have been recommended from earliest times as antidotes for animal poison are worthless, as they have not the properties commonly ascribed to them. The paucity of remedies is so great that alcohol is the one which comes most quickly to the mind of those who have been taught in the traditions of the past, and who are not fully aware of its action on the human system. We shall endeavor to show that the action of alcohol is not helpful; on the contrary it is really detrimental, and also that there is a better way out of the difficulty.

If we get a splinter in the body, vital energy is aroused to get rid of the offending substance, inflammation is set up and sloughing goes on until the splinter is voided. If the splinter is covered with acrid material, the same process is intensified and nature endeavors to eliminate the offending substance through the natural excretions. Upon the peculiarity of the material depends the direction of this elimination.

It is well known that some poisons are thrown off by the kidneys, some by the lungs, while others again are attacked by all the emunctories. The difference in the power of the system to absorb different substances, appropriate whatever can be utilized, and throw off whatever can not be used, is sometimes called idiosyncrasy, but more properly it may be called vital resistance, and upon the integrity of this power rests the ability to combat disease in all its forms, whether it be the absorption of any animal virus or the poison resulting from undigested food. This ability is in proportion to the integrity and soundness of every tissue and organ of the body. This may be illustrated by the fact that with a person suffering from kidney disease, which necessarily impedes elimination, the ordinary effects of a poison are intensified; therefore whatever aids in the promotion of good health, or in other words, the normal action of all the functions, will contribute to the safety of the individual in any and every emergency.

When a person dies from the effect of poisoning, it is simply because the system was unable to eliminate the offending substance and was exhausted in the effort. There is a tolerance of some substances which frequently results in chronic disease, and again it is shown in what is called the cumulative effect or acute disease.

Those who would hold that a substance is at one time a medicament, and at another time a poison, have much trouble in drawing the line between the beneficial and the poisonous effect. The idea that poisonous substances act on the system is responsible for many grave mistakes, whereas always and under all circumstances it is the system that does all the action.

There might be some excuse for the idea that disease is an entity, from the facts that have been brought to light by the germ theory, but this theory is of recent date, while the entity theory is as old as superstition.

Snake poison, which may be cited as a type of other animal poisons, takes effect through the circulation, and acts by paralyzing the nerve centers and by altering the condition of the blood. In ordinary cases death seems to take place by arrest of respiration from paralysis of the nerves of motion. The poison also acts septically, producing at a later period sloughing and hemorrhage.

Dr. Calmette, a noted French scientist, claims that what is poisonous in the snake's bite, is not the venom absorbed into the blood, but a principle which the blood itself has developed out of the poison. This would necessitate very quick action when the poison is inserted in one of the large veins, as that is followed by instant death.

The following cases fairly represent some of the tragedies that are occurring in our everyday life.

A man 60 years old falls and dislocates his finger, he goes to the hospital, where in a short time he dies from blood-poisoning. . . . Another man 48 years old, many years a wine merchant, whose great toe was severely crushed by a heavy man stepping on it, was taken with blood-poisoning and in spite of all treatment, even to the amputation of the leg, he soon succumbed to the disease. . . . A young woman 24 years old, picks a pimple on her chin and at once her face begins to swell. In vain was all medical treatment, for in a few days she died in terrible agony. . . . About a year ago there died in Brooklyn, N. Y., a physician in his 38th year, who six years previously received a slight scratch in his hand while performing a postmortem examination. All that medical science could suggest was done to no avail. . . . In the summer of 1896 a young woman 22 years of age was bitten on the leg by an insect. Several physicians were called in but their treatment gave no relief; blood-poisoning set in; it was decided to amputate the leg, but before it could be done she died. . . . In July, 1896, a veterinary surgeon 34 years of age, while removing a cancer from a horse pricked his finger with his knife. The wound was so slight that he forgot all about it. A few days later blood-poisoning set in and in a short time his end came. . . . Some forty years ago a man named Whitney was teasing a rattlesnake in a Broadway barroom, was bitten by the animal and, though whisky was poured down his throat by the quart, all was in vain and he soon died.

Such results seem entirely unnecessary were the proper course pursued, and at the same time they are a fearful commentary on the medical resources of the day.

The latest researches in regard to alcohol reveal it as a poison to the human system in whatever way it may be diluted or disguised. Its effect is always the same in proportion to the amount taken. It is impossible to habitually use it in any form, even in small quantities, without disease and degeneration resulting therefrom. When taken into the stomach the action is the same as with any other narcotic; the meaning of this word is *to become torpid.* It benumbs the nerves of sensation, and thus the vital resistance to any offending material is reduced, and while the patient *feels* less of any disturbance the real harm goes on with accumulated force because of the lack of vitality and non-resistance of the nervous system. This loss of control is readily seen in the conversation of one who has taken what is called "a little too much." The inhibitory power of the brain is diminished.

When the body is in the throes of a vital struggle with a virulent poison it would seem to any unprejudiced mind, the height of folly to further weaken the vital resistance by the administration of any narcotic, and especially alcohol.

The eminent German, Professor Bunge, says, "All the results which on superficial observation appear to show that alcohol possesses stimulant properties, can be explained on the ground that they were due to paralysis." . . . Professors S. Weir Mitchell and E. T. Reichert on "Researches on Serpent Poison," make this notable statement: "Despite the popular creed, it is now pretty sure that many men have been killed by the alcohol given to relieve them from the effects of snake bite, and it is a matter of record that men dead drunk with whisky and then bitten have died of the bite." . . . Says Dr. Richardson, "Even a small quantity of alcohol affects the acuteness of vision."

Testimony of the most reliable character, to the fact of the injurious action of alcohol in disease could be quoted *ad libitum.*

As a great contrast to the weakness of the mass of our people who are drug-takers and alcohol-consumers, and who are liable to almost any epidemic that comes along and quickly succumb to a serious injury, may be mentioned the Turkish soldiers of today, who know nothing of drugs as we use them, and never use alcohol in any form. During the late controversy with the Greeks, one of them was reported as having been shot in the stomach, remaining in the ranks and afterward walking ten miles. Another one who was wounded twice in the legs and once in the shoulder, continued attending to his duties for twenty-four hours, until an officer noticed his condition and ordered him to the hospital. The heat was tremendous but the troops endured it without complaint, and the doctors are astonished at the wonderful vitality of the wounded Turks, who recover with remarkable rapidity. This with good reason is attributed to their abstemious lives.

It has been stated that the Moqui Indians handle the rattlesnake with impunity, and are not inconvenienced by the occasional bite of the animal.

The rational treatment of animal poison is to endeavor to prevent the entry of the virus into the circulation, to neutralize it in the wound before it is absorbed, but when it has entered the system then everything should be done for its elimination.

The most powerful aid to the human system, and the most perfect eliminator known to man is heat. It is used with much advantage and great success by means of water, both internally and externally, but above all is its use by hot air, as in the Turkish bath, which works in harmony with every natural function, promoting the action of all the secretions and more particularly the excretions. By this means will the system unload itself of an accumulation of impurities in an incredibly short space of time, while the heat aids in destroying whatever there may be of virus therein.

Calmette, whom we have previously quoted, has shown that whatever be the source of snake venom, its active principle is destroyed by being submitted to a temperature of about 212 degrees for a variable length of time.

In the not remote future thousands of human beings will owe to the Turkish bath not only an immunity from disease in general, but also an escape from the horrors of a premature death from hydrophobia, the poison of snake bite or the slower action of infectious disease.

The mass of testimony that has been accumulating for over thirty years past is more than sufficient to convince any reasonable mind that is willing to examine the facts.

The medical profession has searched the world over and under for the means of controlling disease, while within the human body itself lies the vital power which needs only to be cultivated and exalted to its true function to banish the mass of disease from the land.

THE THERAPEUTICS OF ALCOHOL IN DISEASE.

Presented in the Section on State Medicine, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, June 1-4, 1897.

BY J. B. GARBER, M.D.

DUNKIRK, IND.

Ever since the days of Æsculapius, the "Blameless Physician" who went about healing and raising from the dead until finally killed by the thunderbolt of Pluto, the progress of medicine has been a struggle. Its history reads almost like a fable. In those days great temples were built in honor of this Father of medicine, and even snakes were believed to receive healing power from his hand. These endowed serpents were sought after by the Greeks and Romans during epidemics, in the hope of their being able in some way to allay suffering and drive away disease.

On this shaky foundation began the struggle of scientific medication, and in this early beginning we find empiricism to be the key-note of therapeutics. Remedies were used in the treatment of disease that possessed a supposed medicinal power or charm that would in some way bring about a cure. Those who practiced medicine were usually an uneducated class of barbers or quacks, who had more influence from the appearance of their dress than from their learning. The same may be said of the pupil, whose student life was judged more from the number of scars on his body than from his profound knowledge.

Yet in all this ignorance and mysticism we find here and there a bright light who would shine out from among the darkness and shadows around him and bring forth some new medical idea or theory that has stood the test of ages. We shall refer to a few as we pass. Vesalius, who after the publication of his great work on anatomy became physician to Philip II., and whose useful life was cut short by his being shipwrecked on the Island of Zante as he was returning from a trip to Palestine; Paracelsus, who was the greatest military surgeon of the sixteenth century, even though he burned the books of Hippocrates and Galen in contempt. We need but mention such names as Harvey, Paré and Jenner, whose great lifework we celebrated so fittingly at our last meeting. These able men with many others have left "footprints on the sands of time." And among the great constellation of medical stars we find some of lesser light whose brightness has long since faded. Hence we naturally think of Hahnemann, who was born in the year 1755, and after practicing medicine for ten or twelve years without success, began the translation of medical books, and when he came to the subject of Peruvian bark became so mystified that he began taking repeated doses to find out its action on a person in health; and while under its tonic influence his mind became so clouded that he gave to the world his theory of *similia similibus curanter*.

The blazing glory of this unscientific principle has long since faded in European countries, and its American brightness has been waning until at the present time we can find only here and there a disciple who is bold enough to announce on his office sign the title "Homeopathy." It now stands on an equality with "mesmerism," "Thompsonianism," "faith cure," "specific medication," etc.

Thus we see what a struggle scientific medicine has had in the past, and is it any wonder that it has come down to us, at the close of the nineteenth century, laden with errors and extravagant ideas in reference to the therapeutics of many remedies?

We hear it said that surgery has made great progress in the last few decades. The same can be said of therapeutics. Think of the shotgun prescriptions of the past. Who would dare write one today? The old "ten, ten" is written no more. The "thumb-lance" has taken its place among the curiosities of relic collectors.

The striped pole of the barber has lost its original significance. Yet while great changes have taken place in the vast domain of medicine, some therapeutic agents, by the great hold they have had on the popular minds of the laity and some physicians, have held on remarkably well.

The most important of these, and the one that concerns us most in this paper, is alcohol, for in some form it has retained a place in therapeutics ever since the people were advised to "take a little wine for their stomach's sake."

The distillation or production of alcohol originated, no doubt, among the Chinese; but the term came with other chemic knowledge through the Arabs. And notwithstanding the progress of therapeutics, alcoholic prescriptions have kept pace and by many have held their original importance. It is only during the last few years that its use in the treatment of disease has been checked, and for this, thanks be to the American Medical Temperance Association and other similar organizations, and to such noble investigators and experimenters as Richardson, Davis, Kellogg, Crothers and others, whose sole object is the scientific investigation of the subject.

In this work in the past there has been a great struggle on account of the popular ideas of the laity and the teachings of many of our text-books on therapeutics and practice.

It has been demonstrated beyond any doubt that alcohol interferes with normal digestion. In those experiments made by Drs. Chittenden, Kellogg and others, it is conclusively shown that alcohol in any quantity or form taken into the stomach inhibits or neutralizes the gastric juice. Hence the use of alcohol is contraindicated in the treatment of all forms of stomach ailments, whether acute or chronic.

Now, what is the effect of alcohol on the normal resistance of the human body to disease? It is not necessary to refer to the experiments of Berkely and others, and especially those of Frank H. Hamilton, for every physician who is a general practitioner has had frequent opportunities of observing how readily those who are habitual drinkers succumb to disease. This fact is well demonstrated in military life, as well as by those who endure great hardships in exploration and navigation; neither can alcoholics stand the extremes of heat and cold as well as the non-alcoholic.

In shock it is of no benefit and adds greatly to the danger. The same is true whether the shock is accidental, surgical, anesthetic or toxic.

Now, lest our paper should be too lengthy, we will hasten to a series of conclusions in regard to the therapeutics of alcohol that we believe are so well established on scientific principles, and as the result of the most scientific investigators of the present day, that they will not be questioned, and if so, then in the light of scientific investigation can easily be defended.

1. Alcohol is an anesthetic instead of a stimulant, and the apparent stimulating effects of its use are delusive.

2. The beneficial effects attributed to its use by alcoholic advocates are due to its paralyzing influence on the nerve centers.

3. Its use greatly interferes with the elimination of urea and other poisonous products, thereby rendering the system more liable to disease.

4. It impairs the co-ordinating powers of the brain and diminishes cerebral activity to such an extent that we have an abnormal action of the nerve centers.

5. It is of no benefit in any of the acute diseases, but greatly complicates the conditions and renders the chances of recovery much less than without it, and to use it in chronic diseases only adds fuel to the fire and substitutes a disease of alcoholism for the one under which the patient is suffering. And if it is of any benefit, it simply keeps up an anesthetic condition of the nerve centers to such an extent that the patient is not conscious of his sufferings.

6. Therefore, we believe that in the scientific light of the closing of this century alcohol should be classed among the anesthetics and poisons, and take its place in therapeutics along beside chloroform, cocain, morphin, chloral, etc., and that our success as physicians will be much better if we abstain entirely from its use in the treatment of disease, and that the beginning of the twentieth century will mark an era in therapeutics.

The shadows of the empiricism of the past shall give way to the light of the scientific medication of the future.

THE TREATMENT OF DIPHTHERIA WITHOUT ALCOHOL, WITH REPORT OF CASES.

Presented to the Section on State Medicine at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY SERAPH FRISSELL, M.D.

SPRINGFIELD, MASS.

That diphtheria is an infectious disease, with a specific poison, is universally believed by the medical profession. Whether there are two forms of the disease, the result of different bacteria, is still a mooted question. I believe there are two forms. Just at present, quite as much attention is being given to the treatment as to the nature and cause of the disease. And while the war of words is still raging, and clinical reports both favor and oppose the antitoxin treatment, while judges as well as jurors disagree as to the merits and demerits of this new remedy, I find that whichever line of treatment is followed, the greater part of the medical profession still cling to the belief that alcohol, usually in the form of whisky, is a necessity. Believing that alcoholic stimulants are *not* necessary, but rather are injurious in diphtheria, my purpose in presenting this paper is to call your attention to a line of treatment less dangerous, and attended with better results than when alcohol is used.

Previous to commencing in general practice, I had seen less than half a dozen cases, including an attack I myself had. The first was soon after the disease appeared in the United States in 1856. The case was that of a young lady, a member of a family all suffering from throat trouble, and who had had a similar attack the previous winter. I well remember the white glistening membrane covering the lips and tongue, and its beaded appearance, but I know nothing of the treatment.

The attack from which I suffered was during my college course in 1873. At that time I was with a homeopathic physician who gave me some pink powders. Not satisfied with the results, I applied to a physician of the regular school. He prescribed tinctura ferri chlor., with potassii chlor., also quinia powders and a generous diet. His directions were, "Eat, eat all the beefsteak you can." For the first day swallowing was exceedingly difficult and painful, but I persevered and made a rapid recovery, with no symptoms of heart failure; no whisky or brandy; no alcohol except that in the tincture of iron. The treatment of the three cases which came under my observation while in hospital and dispensary practice was similar to the foregoing, with local applications of glycerin and tannic acid added.

Case 1.—My first case after entering on general practice was that of a young woman student, 16 years of age. Her home at the time was a public board [illegible] sease wh
first seen was not far enough d [illegible] ts natu
and as sore throats were pre [illegible] rgle a

gave quinia powders. I did not see the patient the next day. The third day I was much startled to find the throat and tongue covered with membrane. Three years before, diphtheria had prevailed in the place and many cases proved fatal, one of the leading physicians having lost two children. So alarmed were the people that it was difficult to find any one willing to care for a person sick with the disease. Fortunately for my patient, as well as for myself, two sisters assumed the duties of nurse.

The following were the prescriptions given:

R.	Tinct. ferri chlor	ʒij	8 00
	Potass. chlor	ʒj	4 00
	Glycerini	℥j	32,00
	Aquæ puræ q. s. ad.	℥iv	128 00

Misce, Sig.: Gargle throat every two hours, also take one teaspoonful diluted every four hours.

R.	Quiniæ sulph	gr. xxx.
	Ft. chart. No. xx	

Sig.: One powder every four hours.

Two and three times a day I made applications of glycerin and ferri persulph. to the throat. The latter I by accident found to give better results than tannic acid. No alcoholic stimulants were given, but the patient took from five to eight goblets of milk and two to four eggs every twenty-four hours.

Dishes and spoons were retained in the room and thoroughly cleansed, and the most scrupulous care was exercised about the sputa. External applications of sliced lemon were made to the throat. Twice alcohol was used as a gargle.

There was great excitement among the boarders when it was known that no form of alcohol was prescribed. The mistress of the house informed me that "all the doctors in town and the best doctors in New York City gave whisky or brandy in diphtheria; that her nephew was then sick with diphtheritic sore throat, and was taking whisky by his physician's order." My reply was: "You tell me all the doctors here give whisky, but their patients do not all recover; I know that one physician buried two children with the disease. No doubt they had plenty of whisky. This being true, if my patients die without whisky, I can not see that the physicians have any reason to criticise me, or my line of treatment."

Previous to this conversation, I had consulted various authors on the treatment of this disease, and found the majority of them favored the use of alcohol in some form; a few did not, and these reported no more fatal cases than the others.

I also found that the authors who recommended whisky, brandy, etc, in diphtheria, recommended the same in other diseases that I had successfully treated without their use. Furthermore, in my own case stimulants had not been prescribed and I had taken nothing of the kind. I had therefore decided not to give alcoholic stimulants in this case. The following day I learned there had been so much said to the sisters who had been caring for my patient, that there was some whisky put in her milk. She detected it and asked whether I ordered it? On being answered "No," she said, "Then I'll not touch a drop," and did not.

My patient made a good recovery. Though a delicate girl, she showed no symptoms of heart failure, did not lose color, and to all appearances had gained in flesh. Her recovery was so rapid, and she looked so well, it was a common remark that "Miss Fannie could not have been very sick." If there was anything further needed to strengthen my belief that whisky was needless in diphtheria, it was the marked contrast between *my patient's* recovery and looks, and the young man who had taken the whisky treatment.

Case 2.—May 20, 1890, I was consulted by the janitor of our building, for sore throat. (From experience gained as a nurse during an epidemic of diphtheria a *few* years before, he had diagnosed his own case before seeing me.) Examination revealed inflamed fauces and gray patches on tonsils. I prescribed the same medicine as in Case 1, using the gargle every half hour; the iron internally every hour; external applications of salt pork with black pepper to the throat; plenty of beefsteak; room to be disinfected with chlorin gas once in eight hours. My patient, whose room was in the building, decided that with his previous experience, he would care for himself, and promised to take the medicine faithfully as prescribed. This he did, but after twelve hours, I became dissatisfied with results and decided to try the chlorin treatment. I commenced using chlorin water, preparing it myself so as to have it of greater strength than the officinal: Aquæ chlorini ℥iij; glycerini ℥j. This was used as a gargle every half hour. Also one-half to one teaspoonful diluted, every two hours; iron and quinin every four hours alternating. A marked improvement followed. The evening of the third day found the throat apparently clear, and everything indicated a speedy recovery. With the relief of mind which came from this knowledge, the patient retired at ten o'clock and awoke at four in the morning, when he found the membrane again forming. That day, without my advice, he took a cathartic. When I next saw him, he complained of a burning sensation in the esophagus and stomach, with nausea and vomiting. Later the same burning in the bowels. For about thirty hours he was unable to retain food or medicine. Pieces of membrane resembling cooked macaroni were vomited. Various remedies were given to check the vomiting, but nothing proved effectual, until vegetable charcoal was used. From this time the vomiting ceased, and three evacuations of the bowels followed in about fifteen hours. The first two were described as burning like fire; the third more natural.

The symptoms from this time were much more favorable. While vomiting the posterior nares became infected, as did the larynx. The latter was relieved by inhaling chlorin gas, sufficiently strong to produce spasmodic coughing, when the membrane was dislodged and expectorated. I dismissed the case in ten days.

For the first two and a half days, the patient ate nearly three pounds of beefsteak per day. Very little if any food was retained the next two days; after the vomiting ceased, a moderate quantity was taken. Naturally there was some prostration from not taking food for so long a time, as well as from the disease. There was no whisky and no heart failure.

Case 3.—Miss G. consulted me July 4, 1890. She had recently been with a brother and nephew who had diphtheria; both cases fatal. Had dressed the nephew for burial, putting on stockings when the nails were loose. Had taken whisky as a preventive. Sulphur had been used for disinfecting attendants and premises.

Examination showed the throat very much congested, but no membrane visible. The night before she had used kerosene oil for external application to throat and she wished to use the same again. I made no objection. I prescribed the same remedies, disinfectants and food as in Case 2.

July 5. Throat much as the night before. Blisters had formed on the neck, from the kerosene oil. No membrane visible until the third day. Later I found that swabbing the throat spread the disease, and omitted this part of the treatment, but continued gargle and medicine every half hour.

During the second week, pieces of ice were given for a few hours, resulting only in incrasing and thickening the membrane; the same results from a dish of ice-cream.

At this time the membrane covered the tongue and so nearly filled the throat, that there was little space for swallowing. This condition was relieved by local applications of papoid. I also gave papoid, gr. iss to v, every two hours. A local application of mercuric bichlorid (1 to 1000) dissolved the membrane like snow in hot water, but the surface beneath was left in such a sensitive condition, that I did not dare continue its use, fearing spasms from contact of food with the denuded tissue.

The nasal passages to which the disease extended were irrigated with chlorin water by means of an elastic catheter attached to an ordinary hard rubber syringe, with the piston removed. For more than three weeks the treatment was continued every hour or half hour.

During the earlier stage of the disease, notwithstanding my strict orders, the patient was careless about the sputa, and I am confident that later this was the cause of re-infection, since it is the only case in my practice where the disease continually recurred after it was apparently under control.

It was not till the patient was removed to another room, and her bed, bedding and room thoroughly disinfected with chlorin gas and bichlorid solution that the disease was finally conquered after four weeks sickness. This case was followed by paralysis.

When the agent for the Board of Health disinfected the premises, I am informed that he said he "had noticed where chlorin was used the patient was often paralyzed."

I inquired, "if it was suggested to the man, that possibly where it was not used sometimes there were funerals?"

Cases at Mount Holyoke College, South Hadley, Mass.—In five of the six cases which occurred among the students at Mount Holyoke College, in 1891, at which time I was the physician, I followed the same line of treatment as in the last case reported. In the sixth case, the young lady had chronic catarrh and the nasal passages proved the point of attack.

Laryngeal obstruction developed the third day, and the patient was in danger from suffocation. Chlorin gas cautiously used gave relief. This case proved very stubborn.

On account of the catarrhal condition, the gargle and douche of chlorin water produced irritation, and a solution of mercuric bichlorid was substituted 1 to 100, for the nasal passages and 1 to 62 for the throat. My authority for using this strength, was cases reported by Dr. F. H. Peck of Clinton, N. Y., in the *New York Medical Record*, Jan. 31, 1891.

These applications were made every two hours. A small swab of absorbent cotton with four drops of the solution was used each time for the throat, then burned. An atomizer was used for the nasal passages.

In this case it was twelve days from the inception of the disease until the parts were entirely free from the membrane. Three days later, the patient went to the eastern part of the State (a journey of more than one hunded miles), where she spent one week, when she returned to the college and resumed her school duties.

Not one of the six young ladies showed serious prostration. After the first twelve hours, they were usually ready for their three meals, with two or three lunches. Two of the meals, sometimes all three, consisted of a generous piece of beefsteak or roast beef, with other articles of diet to suit their appetite, while the lunches were usually milk with plenty of cream and eggs. It was one of their pastimes, to make out their bill of fare for the coming meal.

Dr. Edward Hitchcock of Amherst College, Chairman of the Sanitary Department, Dr. G. W. Davis of Holyoke, and Dr. G. G. Hitchcock of South Hadley Falls, saw these cases (but not at any time when the exudate was at its worst), and all three pronounced the disease diphtheria. Prof. Hitchcock said to me: "I presume you give plenty of whisky?" The others made similar remarks. My reply was, "Not one drop; my diphtheria patients have food, not whisky."

Like my first case reported, these young ladies made rapid recoveries. They had so few of the complications usually following the disease, that some of their relatives questioned my diagnosis.

A local paper reported ten cases with one death. Fearing this would be the means of breaking up the school, a report went out from the college, that there neither was, nor had been a case of diphtheria there. The question may naturally arise, why was not the school discontinued? My answer is, because of the source of the infection, and my faith in chlorin gas as a sure disinfectant. Had I found that the disease resulted from defective sanitary conditions, the only thing would have been, to have closed the school; but with the third case, I traced the source to a room, whose occupants had been in communication with relatives whose son had diphtheria.

The following interesting case was the first in which I used the chlorin treatment:

July 9, 1888, I was called at 10 P.M. to see Annie B. aged 6 years. She had had fever for two days. The parents had given aconite, but the child had continually grown worse. Her breath was very offensive, and strongly diphtheritic, and the glands about the throat swollen; tonsils so swollen I could not see beyond. Temperature was 103 degrees; no membrane was visible. I prescribed a solution of tincture ferri chloridi and potass. chlor. with glycerin every four hours, alternating with quiniæ sulph. gr. j. July 10. Patient was much worse; temperature 104.2 degrees; gums and lips cyanotic. Acting on the suggestion of an old practitioner (Dr. M. Calkins, Springfield, Mass.), whom I knew did not favor giving whisky in diphtheria, I put my patient on the following:

R.	Aquæ chlorini	℥iij	96|00
	Glycerin	℥j	32|00

M. Sig. Gargle throat every half hour, also one-fourth teaspoonful diluted, internally, every hour.

I continued the iron and potassa solution alternating with the quinia, every four hours. The rooms were to be disinfected every eight hours with chlorin gas. All the beefsteak the patient would eat was given. This treatment was continued seventy-two hours. The last eight hours the mother said, "they could hardly rouse the child she was so sleepy, and sometimes she fought like a little tiger." At times she was troubled for breath. While gargling her throat, she asked her mother, what made her keep spitting up skin.

No doubt this was membrane. Her mother gave little thought to the child's question, therefore neglected to save a specimen for examination.

After the fourth day, the temperature gradually fell to 99.5 degrees, then to 99, where it remained for days, and was not normal, when I dismissed the case.

I had read much of sudden deaths from heart failure when everything seemed favorable for recovery.

This was such a serious illness, I cautioned the mother at each visit not to allow the child to exert herself. I was informed it was impossible to keep her quiet. The truth of this statement was soon verified, for within a few days I found my little patient playing horse, with string attached to bedpost, herself astride the foot-board.

During her sickness, her uncle, a physician, saw the case. His thermometer registered 105 degrees. He favored whisky and beef tea. As the case was progressing satisfactorily I could see no necessity for whisky, and so long as the patient was eating a pound of steak a day, there was no need of beef tea.

Later the father informed me that for seven days the child averaged a pound of steak a day. Previous to her sickness she cared very little for meat.

My patient made a rapid recovery, and showed no symptoms of heart failure. During her entire sickness there was no whisky nor alcohol in any form used, excepting in the tincture of iron.

In treating diphtheria cases, two things I consider quite as important as medicine, viz., the disinfectants used and plenty of wholesome food, especially meat. After eight years experience with chlorin as a disinfectant, the favorable results following its use prompts me to say that I believe there is nothing more effectual. I have yet to learn of the first case of infection from any of my diphtheria or scarlet fever patients since using it.

The following proves its superiority to sulphur.

In Case 3, Mrs. E., at whose home my patient was during her sickness, showed no symptoms of the disease for nearly two weeks. Then for three mornings in succession I was aroused at five o'clock to go to her, as she feared diphtheria. During the day, under treatment, all symptoms would disappear. After the third call, I made particular inquiries and found the woman had been sleeping those three nights in the same room that my patient had for two nights occupied, after coming from the house which had been disinfected with sulphur. I ordered the room and bedding fumigated with chlorin gas. This was done and there was no further complaint from the occupants.

The cases at Mount Holyoke College were reported to the town authorities. In conversation with one of the gentlemen, he referred to the ill success in disinfecting a dwelling house where diphtheria had prevailed. It was almost rebuilt before immunity was secured. Carbolic acid and sulphur were among the disinfectants used. At the college chlorin gas was my only reliance. As soon as I decided that my suspicion as to the nature of the disease was correct, the young ladies were removed to the hospital department and nurses procured. My directions were to use the gas in the patients' rooms every six hours; also use it freely in the hall from which the rooms opened. On making my visits before leaving the hall a fresh supply of gas was prepared and my clothing disinfected.

The rooms occupied by the patients before they were taken to the hospital apartments were disinfected in the same way; also the room where the disease first appeared. After the patients had recovered, the apartments they had occupied with the furnishings were thoroughly disinfected. The mattress and curtains in only one room were burned. There were no more cases of diphtheria although the rooms were used after a week's time.

In regard to food, if diphtheria is first a local disease (usually invading the throat and air passages), I ask what is to hinder stomach and intestinal digestion?

I know from experience that mastication and deglutition is attended with pain. Yet I believe in, and insist on my patients taking nourishing food from the first, if only liquids.

In a few hours the throat seems less sensitive and beefsteak, with other solid food, can be taken by older children and grown people, unless medicines are given which destroy the appetite and interfere with digestion.

By taking food the system is fortified against the disease, the stomach is in a better condition for medicine, the secretory and excretory organs stimulated to perform their natural functions and the diphtheritic poison more rapidly eliminated from the system.

That alcohol will kill diphtheria bacilli I believe, so will chlorin gas. The latter is a disinfectant and germicide; besides, the hydrochloric acid which I use in its preparation, is a normal constituent of the gastric juice, and aids digestion rather than retards it.

Whisky, like any alcoholic stimulant, congests the the mucous membrane of the stomach, retards digestion, destroys the appetite, and paralyzes the nerves.

So many fatal cases are reported where whisky is given, it is my belief that sometimes it is the whisky which causes heart failure rather than the disease.

In closing I will say that, though differing from the general practice of the medical profession, I have never prescribed alcoholic stimulants in diphtheria. and I have never seen reason to regret the course I have taken.

Let us have a Department of Public Health!

CONCEALED ALCOHOL IN DRUGS.

Presented to the Section on State Medicine, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY T. D. CROTHERS, M.D.

SUPERINTENDENT WALNUT LODGE HOSPITAL.
HARTFORD, CONN.

The fact is well known that nearly all proprietary drugs contain large quantities of spirits, particularly the bitters and tonics that are advertised so widely Several authorities have made extensive examinations of drugs advertised as temperance drinks and free from alcohol, and in every instance have found spirits from 3 to 50 per cent. of volume, literally ranging all the way from the lighter beers up to the strongest alcoholic drinks in common use. Dr. Bradner has published tables of these drugs compiled from the reports of the Massachusetts Health Board and the examination of State chemists in different parts of the country. His paper appeared in the *Journal of Inebriety* for January, 1890, and the second paper on this subject will be found in the July issue of that journal. These papers bring out the fact, not well known, that nearly all the more prominent proprietary drugs on the market contain large quantities of alcohol.

How far these drugs depend on alcohol to increase their attractiveness and sales is not known, but it is evident that many of the widely used drugs would have no demand if it were not for the alcohol which form the bases of the combination.

The *Medical Press and Circular* and the *Lancet* have called attention to the great danger from the so-called temperance drinks advertised as antidotes for inebriety. An examination of many revealed cocain, opium and alcohol in nearly all of them. Several instances are given of persons who used large quantities of these drugs under the impression that they were cured of the alcoholic crave and were building up against it in the future. In reality they were worse and more incurable than they would have been, using spirits alone.

One case was cited of the death of a man who used large quantities alone of "Seaweed Tonic," which contained 40 per cent. of alcohol. He was under the impression that he was being cured of inebriety, when suddenly delirium tremens came on and he died.

In this country the substitution of ginger compounds for alcoholic drinks are common and always end disastrously, leaving the victim worse and more incurable.

Coca wine preparations are also dangerous, and although I have used them in the first period of withdrawal of alcohol for the treatment of inebriety, it was evident that in many cases they would completely take the place of alcohol and require as much difficulty to remove as the spirits.

The dangerous credulity of professional men in freely endorsing drugs for this or that affection is very common in this country. One of the latest examples of either stupidity or duplicity, is the warm endorsement of a drug by a noted temperance revivalist as a great tonic to be used by all persons who are worn out from alcohol and other causes. Repeated analyses have revealed the fact that this drug contains 21 to 28 per cent. of alcohol, and it is literally stronger than most of the alcoholic drinks in the market. While these *facts have been stated many times before, they seem* not to have been accepted by the general medical public. The older theories that alcohol is a medicine and food, in some unexplained way still continues, and the use of spirits in drugs of all kinds seems not to be thought harmful in any particular way. The gold cures for alcohol and opium contain in many instances these drugs concealed, and while in use completely satisfy all cravings and give the person a false sense of security and restoration. A very important question has been repeatedly raised and answered differently by persons who claim to have some expert knowledge. The question is, can strong tinctures of common drugs be given in all cases with safety; tinctures of the various bitters which contain from 10 to 40 per cent. of alcohol, and are used very freely by neurotic and debilitated persons? It is asserted with the most positive convictions that such tinctures are more sought for the narcotic effect of the alcohol than for the drugs themselves.

In my experience a large number of inebriates who are restored, relapse from the use of these tinctures given for their medicinal effects.

A neurotic who takes bitters or vegetable extracts for any purpose soon turns to wines and then stronger liquors for relief and becomes worse than before. This does not occur in all cases, the effect of the bitters is often repelling, the alcohol causes a headache and they are abandoned.

Alcoholic extracts of any kind used as tonics, diuretics or cathartics are always dangerous and uncertain. The alcohol they contain is, in most cases, very cheap and impure and more dangerous than the spirits used as beverages.

In a recent investigation it was shown that wood spirits were used to make a patent bitters, and the steady increase of the demand for this form of spirits beyond the known requirements of the arts point to its use in drug extracts. There are no evidences of this use, especially in well known drug houses, but the temptation to add to the profits of a drug by using an alcohol on which there is no duty and one with a duty of 90 cents a gallon is very great. Nevertheless, as physicians studying the symptomatology of cases, we are often confronted with a new class of symptoms, where tinctures are given freely and the effects are unexplainable.

In a recent case of influenza where tinct. cinchona was used freely there was mild delirium and irritation, which subsided when the cinchona was stopped. In another case a secret drug was used and the continued stupor and dulness which followed suggested an opiate. An analysis revealed morphia in large doses. It is easy to see how quickly an addiction to such a drug would be created, especially in a neurotic.

I have seen two cases who were suffering from some bronchial irritation, addicted to a secret cough remedy which contained morphia. They suffered, and with great difficulty were made to abstain from the use of the drug.

A very excellent clergyman had certified to a cure of consumption by a certain cough drug, but he could not keep from using it more than a day or two. After two years of continuous use of the drug he became very ill and was treated with morphia by a physician. He recovered but became a morphia inebriate, the beginning of which was the cough medicine at first.

The question is raised, how much alcohol can be used as a solvent in drugs without adding a new force more potent than that which is brought out by the alcohol? Opinions of experts differ. One writer thinks 10 per cent. of alcohol in any drug will, if given any length of time, develop the physiologic effect of alcohol in addition to that of the drug. An English writer says that in some cases a 5 per cent. tincture is dangerous from the alcohol which it contains.

There is some doubt expressed by many authorities as to the potency of a drug which is covered up in a strong tinture. It is clear that the value of a drug is not enhanced, and it is certain that a new force producing or exploding agency has been added to the body.

In experience, any drug which contains alcohol can not be given to persons who have previously used it without rousing up the old desire for drink, or at least producing a degree of irritation and excitement that clearly comes from this source. It is also the experience of persons who are very susceptible to alcohol, that any strong tincture is followed by headache and other symptoms that refer to disturbed nerve centers.

In many studies I have been surprised at the increased action of drugs when given in other forms than the tincture. Gum and powdered opium have far more pronounced narcotic action than the tincture. Yet the tincture is followed by a more rapid narcotism, but of shorter duration and attended with more nerve disturbance at the onset.

I am convinced that a more exact knowledge of the physiologic action of alcohol on the organism will show that its use in drugs as tinctures are dangerous and will be abandoned.

There are many reasons for believing that its use in proprietary drugs will be punished in the future under what is called the poisoned act. It is certainly clear that we are now at the beginning of the study of alcohol and our knowledge of its effects.

THE ETIOLOGY AND THERAPY OF TUBERCULOSIS.

Presented in the Section on State Medicine, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, June 1-4, 1897.

BY H. B. WEAVER, M.D.
ASHEVILLE, N. C.

All intelligent therapeusis must necessarily have as a basis a correct understanding of the etiologic factors that enter into the morbid complexus which it is intended to combat. That there can be no rational treatment of tuberculosis without a correct knowledge of its pathology is evident. On the other hand, it can not be claimed that the histogenesis and progress of the various elements of tubercle are thoroughly understood, although all admit that many facts bearing on it are well determined. One of these facts is, that a vegetable parasite, infective in its nature, is in some way causative. Whether, however, the bacillus tuberculosis of Koch is the fundamental primary cause of this morbid complexus is not so generally acknowledged.

Many eminent pathologists point out the fact that not only the minute tissue changes, which identify the tubercular processes, are virtually one and the same, but that these tissue changes are the result of the same parasite—Koch's bacillus. Even if we grant these facts upon a purely histologic hypothesis, yet there are clinical facts observed over and over by the greatest clinicians of today which might lead to a somewhat different conclusion. They insist, and not without the show of facts, as we believe, "that there is in the constitution of the individual anterior to the bacillary infection something that determines the fact of the infection and that largely determines also the course and character of the results of infection. We are aware that this doctrine of diathesis or susceptibility is generally admitted by those who hold the current view. We only wish to demur to the idea of the *subordination* of a *primary* etiologic factor to a *secondary* one.

The lamented Flint, among his latest utterances, while admitting the etiologic importance of Koch's bacillus, said in paraphrase of Shakespeare: "You take away their lives when you do take away the means by which they live." Dr. Andrew H. Smith, in the New York Academy of Medicine, recently said in speaking of phthisis, "The fact should be recognized that tubercle bacilli never become implanted in the healthy system. There is always an abnormal anterior condition, and it is that condition that should receive our attention." "By sufficiently improving the nutrition," says Dr. Smith, "you lift the patient above the plane on which the bacillus flourished." Solis Cohen, in his most exhaustive treatise on tuberculosis, forcibly remarks that, "to make our conception of the disease sufficiently comprehensive, we must include other elements than the bacillus and the changes in cellular structure or chemic constitution of solids and fluids brought about by its activity." He continues: "That condition which makes the human tissue a 'receptive soil'—a favorable 'culture medium' for the tubercle bacillus—that condition which of old was called 'diathesis' or susceptibility, is *itself* a disease, a departure from the *norme*, and I believe it to be the most important element in the morbid complexus termed tuberculosis." "It is the element requiring the greatest care in the prophylaxis, the most intelligent and faithful treatment." We believe that this cachexia, this predisposition which may be inherited or acquired, is a defective nutrition, superinduced by a want of vital energy which has its correlate in the histologic expression, in the place of normal tissue elements, of tissue elements of abnormal condition and lowered vitality. We know that tuberculosis is not the product of a truly inflammatory process, neither is it a neoplasm, for it tends neither to " resolution and repair nor to proliferation and persistence. Its tendency is to destruction without subsequent repair." It is a necrosed coagulation without blood vessels and without cell organization, without life—it is death.

Koch's bacillus, then, though still a power, is no longer supreme, according to many pathologists. Though the diffusion of the bacillus has been proven by laboratory research to be almost limitless, that it is in the air we breathe, in our food and drink, yet how few, comparatively, become infected. It is now proven that the respired air of the consumptive may be breathed with impunity. The sputum must be perfectly dessicated before it can become infectious. There is a later school of pathologists who maintain that the bacillus is not even infectious or contagious; that there are other concomitant bacilli more dangerous in their nature, to which "Koch's is simply the cross-sweeper" favoring their entrance; "that in the more pronounced cases of phthisis with the severe symptoms of hectic are the resultants of these concomitant bacilli only," and that the bacillus of Koch is assigned to simply an accidental rôle, appearing in local manifestations merely, which are well defined and eminently curable; that the disease is nothing more than a scrofulosis. How well founded these views are, remains to be seen. Yet it must be admitted that the trend of modern medicine is toward the doctrine of malnutrition as the fundamental, primary factor in the evolution of the phthisic state, and that the intervention of the bacillus of Koch is the secondary factor in the modification of a process already determined. Therefore, we conclude with Cohen, that when in the course of ordinary wear and tear, or "extraordinary wear and tear, or following inflammation or injury, or from any cause or combination of causes degraded tissue elements have been produced, it is highly probable that the tubercle bacilli or other microbes finding therein a favorable soil modify by their activity the further evolution of the disease." Consequently, in summing up the facts, as reflected by both observation and experience relative to the causation of tuberculosis, we think that we are warranted in the following conclusions: 1, that malnutrition is the starting point of all tubercular process; 2, that while the bacillus of Koch is perhaps the most important of the several microbes that influence the progress of the lesion in the various forms of the disease, yet it does not of itself originate the disease in any form; and 3, that both factors, the dyscrasia and the bacillus must exist in combination before there can be tuberculosis.

THERAPY.

Since tuberculosis is a curable disease; since defective nutrition, which may be either congenital or acquired, is the fundamental primary factor, and Koch's bacillus, which is infective in its nature, is the modifying secondary factor in the causation of phthisis, it behooves us to adopt such means and methods as are at once prophylactic and curative in their nature. To attempt to consider the various agencies, either preventive or remedial, in detail, would far transcend the scope of this paper; therefore we shall content ourselves by referring to those of most vital importance. If there is any principle in medicine established so firmly as to exclude debate it is that which makes the highest degree of nutrition the supreme condition of health.

The province and purpose, then, of modern medicine is to restore. And if there is one thing more than another that distinguishes this age of therapy it is the lessening of therapeutic agents by physiologic methods of therapy. It is doubtless true that the vegetable and mineral kingdoms and the realm of applied chemistry have given us countless remedies of value in the antagonism of diseases, but the "grander and deeper researches of biology, the study of the revelations of our cell-life forces operating within the blood, the life stream of the body, has resulted in far more direct and positive agents, restorative and at the same time vitalizing in their natures, reinvigorating the system and enabling nature to offer resistance to the encroachment or ravages of disease." It is also true that nothing has been more indisputably settled by the modern science of biology than that health or vitality is as truly and as practically the antagonist, as it is logically the antithesis, of disease, of every form of disease, of every course of disease. Again, it is one of the most brilliant of all the demonstrations of modern biology that the principle we call health or vitality is not only centered, as was always blindly believed in the blood, but also that perfect blood is an impregnable citadel, carrying an armament against which the assaults of disease whether by antecedent germs or in consequence of toxins are forever impotent. Here, upon this great truth, it is clear that an infallible hemotherapy might be founded which has been shown to possess the power of, 1, antagonizing specific pathogenic germs; 2, distributing to their ultimate destination nutritive material; 3, stimulating the physiologic functions by normal pathologic influence.

The fact now universally acknowledged by scientists without exception, that millions of pathogenic germs entering into the organism at every breath would go on to immediate destruction of the tissues of the body, is itself an argument *a priori* in favor of the existence in the organism of cellular agents of germicidal resistance to pathogenic germs. This fact was first demonstrated to the world in the discovery of the cellular principle of nuclein, which physiologists found to be the product of the action of the blastema or cell substance of multinuclear leucocytes, or white blood corpuscles on the proteids delivered to the blood from the digestive tract. All peptones are converted into nuclein through their leucocytes. The hitherto mooted physiologic point concerning the assimilability of the peptones is thus explained. Before being cellulized they are foregn bodies and often toxic agents. Therefore nuclein is two-fold in its functions: 1, it has a physiologic function of tissue building; 2, a pathologic function of an antitoxin. In the first all proteids are converted into nuclein by the leucocyte and delivered to the various tissues of the body by the blood. In the second capacity it is the natural enemy of all disease germs. When formed in the blood, as we have said, it is the action upon proteids by the leucocyte. When introduced into the organism it acts in two ways: 1. It immediately excites the osmotic action of each leucocyte, causing it to proliferate or break up into nuclei, which is leucocytosis, the first physiologic step in the resistance of disease, and the fundamental axiom of physiology is, the more active the leucocytosis the greater the vital resistance. 2. It furnishes ready made to the leucocyte material which, under depressed vital conditions, it is unable of itself to construct from the proteids and thus lifts the organism to the physiologic plane, while it so strengthens and increases the leucocyte that it overpowers the toxic germs with which it may come in contact. Every leucocyte if in normal condition is a phagocyte, it has the power of eating up toxic germs and destroying their vitality. Hence this theory of phagocytosis, first advanced by Metchnikoff, has started the profession into the conception of a higher therapy, hemotherapy.

Hemotherapy, blood therapy as the name imports, "is a system of treatment by blood supply, and comprehends also the treatment of the blood fluid itself, its reconstruction and renewal, its cellular alteration and its constituent modification by the introduction of direct biologic agents or substances derived from the blood or tissue, or the introduction into that fluid of chemic and other agents capable of modifying its diseased and altered components, rendering them isomeric and identical with pure and healthy blood." We care not what the agents may be. It may be pure bovine blood or extracts from glandular tissues or the nucleins of Vaughan, or it may be a cultured substance, as those of Koch and Klebs. It must be some substance directed to and introduced into the blood, exerting its known influence therein directly upon the fluid so as to modify for the better, alter and purify, reconstruct and renew that fluid. The fact that some of these biologic or chemic substances other than blood itself are capable of producing these effects brings them under the purview of hemotherapy. The objects aimed at and the effects produced are the same or identical in nature. Hemotherapy seeks to supply blood material, to promote its cellular activity and its germicidal powers. The theory is so palpably clear, so true to the teachings of nature that its wisdom is self-evident.

"Phthisis has its origin in defective tissue-building forces superinduced by privation and depression." It is a popular belief that if food is digested and taken into the circulation that is all that is necessary, but food elements that have undergone thorough transformation in the digestive tract, have been absorbed by the lymphatics and discharged into the blood current, are not yet blood. They are still food and have done the body no good. There are two conditions yet to be fulfilled before this food can benefit the system; a demand on the part of the body for it and nutritive force sufficient to convert such food into tissue. Hence the sheer failure of the food elements, be they ever so well digested and thoroughly nutritive, if they are not appropriated by the body. For this demand, which is dependent on healthful activity both external and internal, and this vital force which resides in the blood cells and is measured by their plenitude and their oxidizing and vitalizing power, are the very things that neither medicine nor diet nor change of air can enable the exhausted functions to reproduce. Oxidation in the lungs takes place in proportion to the amount of space in which the air comes in contact with the blood. When, as is the case with pulmonary tuberculosis, an extended portion of the lung becomes obstructed or the tissue thickened, so that the oxidizing process is to a degree frustrated, nutrition is likewise frustrated and poisons necessarily accumulate in the blood. Under these circumstances when the blood is already surcharged with débris which it handles with difficulty, food crowded into the circulation only aggravates the condition instead of relieving it. Every day the tubercular infection eats away more of the lung tissue and shuts off more of the breath of life from the languishing and non-proliferating blood cells, which thus daily appropriate less nutriment and transform it into less and less of living tissue in every part, organ and nerve of the system, a process which is well called consumption, for the victim is rapidly consumed by starvation; "not for want of food (with which he can do nothing), but for want of breath, for want of lungs. There is no help in him and no human art or power can engender help within him; it must be put in him. Is there nothing that can be done to stanch this flux of life blood?" It is here that hemotherapy comes to the rescue and supplies the great desideratum with her conserved nuclein, in the form of pure bullock's blood or in animal or vegetable nucleins, which may be transfused or introduced through any part of the alimentary tract, which will do the whole work of healthy blood, ready oxidized in spite of inadequate breath; ready vitalized and cell-abundant in spite of exhausted vital energy.

The only practical question remaining is: Can these principles be extracted and preserved in their physiologic environments for therapeutic use? The very scientific researches and trustworthy experiments of Vaughan, Alude, Breckenridge and their colaborers would seem to answer this very conclusively in the affirmative; while the testimony of such distinguished clinicians as Biggs, Conant, Baxter, Bliss, Mays, Waugh, Wathen and a host of others can be taken only in the light of a demonstration of the proposition that in hemotherapy we have the corroboration of Metchnikoff's experiments that it is the principle of leucocytosis, hence phagocytosis, the most valuable method in the modern pharmacopeia. And as phagocytosis is declared to be the basis of resistence of the body to micro-organized disease and that the blood serum has germicidal constituents and that this quality is found in the neuclin, it is reasonable to suppose that hemotherapy or neuclein therapy is a rational procedure in the treatment of tuberculosis.

There is a difference between immunity and cure. Immunity we conceive to be a condition brought about by the introduction into the organism of a modified virus or an antitoxin which so stimulates certain cells that they produce an antidote to the poison. In diphtheria the antitoxin introduced into the body of the child may so stimulate the spleen that it manufactures nucleins in such abundance that they in their phagocytic functions are enabled to swallow up or in some way neutralize the toxins of the micrococci in the throat.

"In tuberculosis nature has attempted to immunize every tubercular subject and has utterly failed. Some step in the process has failed." The process of leucocytosis has been interrupted by want of vital energy or defective nutrition. The leucocytes are no longer phagocytes. "The bacterial poison has been introduced into the body in a form too virulent to be resisted or the cells of the body have been unable, devitalized as they are, to act with normal energy." Hence, if nature with all her resources within the body is unable to combat the disease, then where shall we look for curative substances in infectious diseases? Not to and within the body itself. We must look to some extraneous source. Either we must introduce some germicide formed by other cells outside of the body or employ other agencies for the purpose of stimulating the nuclein-forming cells. Hemotherapy offers us the means which we can utilize, either the bullock's blood or the animal extracts which contain the germicidal essence—the nuclein. We see then that the only germicide from which we can expect any good results must be of cellular origin. We know that the experience of the medical profession for the last twenty years has demonstrated the fact that no known chemic remedy can be introduced into the living organism with sufficient strength to act as a germicide without doing serious harm to the tissues with which it comes in contact. Almost every day we hear of some new discovery of a germicide for tuberculosis, but experience has invariably shown in every case that it was poisonous or not germicidal at all. Hence pet nostrums of various combinations of creosote, terebene, eucalyptus, menthol and the like have been used with all manner of mechanical devices, by the ardent advocates of this local process, without any permanent effect on the tubercular process. The researches of Behring demonstrate that antiseptics, when injected under the skin, reach a fatal dose when one-sixth of the amount which is necessary to prevent the development of the anthrax bacillus, is used. Solis Cohen, speaking of the local use of these substances, remarks: "Those that have been urged or revived since Koch's discovery are principally germicidal agents and are directed against the bacillus. Recalling the location of lesions containing bacillus, anyone at all familiar with the penetrating power of sprays and vapors, under the usual physical conditions, will know how fallacious is this notion." With the possible exception of turpentine (as a type of its group) they have not seemed to me to have the slightest influence over tubercular processes." Now, in the language of Victor Vaughan, "that we have learned that the animal body itself germinates a germicide more powerful than corrosive sublimate, and since we know how to increase the amount of this substance in the blood and can isolate it and inject it into other animals, renewed hope comes to us." In the pure blood or nuclein treatment we have hope of accomplishing the destruction of the specific germs of tuberculosis within the living organism or immunity from their toxic products. If infection occur in healthy persons, their tissues and especially the blood are capable of offering successful resistance and the organism is preserved in its integrity. But in the established disease the resisting power of the patient has been insufficient, either by reason of the organism having been overpowered by excessive quantity of infecting material or by minor resistence on the part of the tissue where the germ gained entrance. It is, therefore, most rational to seek the regeneration of the blood. In addition to dietetic and hygienic management, we look to hemotherapy to bring this great boon to man.

I am under obligations to Drs. Osler, Cohen, Vaughan, Andrews, Biggs, Summers, and others, from whose works I have freely drawn.

A REPORT OF THREE CASES OF TETANUS. ONE TREATED SYMPTOMATICALLY AND TWO WITH TETANUS ANTITOXINS.

BY JOHN E. OWENS, M.D.
ATTENDING SURGEON TO ST. LUKE'S HOSPITAL,
AND JOHN L. PORTER, M.D.
LATE HOUSE-SURGEON, ST. LUKE'S HOSPITAL; ATTENDING SURGEON ST. LUKE'S FREE DISPENSARY.
CHICAGO.

Case 1.—Thomas McG., Canadian, laborer, aged 26. Patient walked into St. Luke's Hospital Oct. 25, 1895, with the following history: Eight days previously he had received a punctured wound of the foot from a nail. The wound bled slightly and he had at once gone to St. Luke's Dispensary for treatment. Here the wound had been freely incised and washed with a strong bichlorid solution and wet bichlorid dressing applied. He had returned each day to have the dressing renewed. The evening before his appearance at the hospital he had noticed some difficulty in chewing and swallowing, and this had brought him to the hospital early the next morning with the remark that he thought he was going to have lockjaw. Examination showed marked trismus, the masseters being tense and hard and the patient unable to open his jaws more than a half-inch, and attempts to separate them forcibly caused pain. His speech was indistinct. An attempt to swallow some water that was given him caused spasm of the pharyngeal muscles and part of the water was regurgitated. The patient complained of lameness in the back of his neck and could not flex his chin on the sternum. Forcible attempts to do so caused pain. Examination of the wound showed an incision about one inch long and half an inch deep in the ball of the foot, dry and clean and with no signs of inflammation. The patient was at once assigned to the surgical ward, the wound enlarged and irrigated with 1 to 2000 bichlorid solution and a bichlorid dressing applied. Chloral, grs. xv, and sodium bromid, grs. xxx, were ordered given every three hours. Attempts to secure some tetanus antitoxins were made at the Health Department and the various laboratories in the city but none could be found. The patient continued about the same during the day except the pain in the face and neck became more severe and began to extend down the back, and deglutition was a little more difficult. Extract of calabar bean was ordered later in doses of a half grain every two hours. Just twenty-four hours after admission the first general convulsion occurred, and they continued to recur at short intervals with increasing severity, involving the neck, thorax, back and abdomen and required chloroform anesthesia. Later the extremities became involved and the patient was in a position of opisthotonos almost constantly when not under chloroform. Finally the diaphragm became involved; sufficient chloroform could not be administered even by artificial respiration to secure relaxation, and the patient died from asphyxiation thirty hours after admission. Cyanosis was intense. The temperature during the entire time ranged from 97.8 to 98·6 degrees. The patient retained consciousness up to two hours before death. An autopsy could not be secured.

Case 2.—J. A., American, cook, age 19, brought to St. Luke's Hospital Oct. 27, 1895. He had fallen between two cable cars in such a position that the guard surrounding the car struck him in the head, pushing him along on the track for some distance. He presented the following injuries: 1. An extensive laceration of the scalp in the left parietal region with a large oval flap 10 cm. in diameter torn up and turned back; the periosteum scraped from a large part of the exposed bone and hanging in shreds. 2. A small laceration at the outer angle of the left orbit, and several abrasions about the face. All the wounds were very dirty but the scalp wound especially was full of the dirt of the street, ground in with such force that the pores of the denuded bone were filled. No fracture was demonstrable and there were no symptoms of intracranial pressure. Patient was conscious and able to talk intelligently.

He was anesthetized, the entire head shaved and the wounds cleaned as thoroughly as possible under constant irrigation. Portions of the scalp, where the dirt was so ground in that they could not be cleaned were excised, as were the torn shreds of periosteum, and the dirt picked or scraped out of the bone. Ample drainage was supplied with gauze and twisted silkworm gut, antiseptic gauze being carried into all the crevices between the edges of the wound and the skull. The flap was then replaced and held in position with a few loose sutures of silkworm gut, no attempt being made at accurate approximation as the tension required would interfere with the drainage. The laceration at angle of orbit and abrasions about the face were next carefully cleaned and the whole side of the head enveloped in a wet antiseptic dressing. Antiseptic irrigation was kept up daily and the patient made good progress, being up and about the ward with no temperature on the sixth day. During the second, third and fourth days the highest temperature was 101.8, 101.2 and 100.4 degrees respectively, coming down to normal on the fifth day. On the seventh day after the injury it was noticed that the patient apparently had a left-sided facial paralysis, as the lines about the cheek and angle of the eye were effaced and the corner of the mouth seemed to droop a little. Upon being questioned the patient said he felt first-rate. The next day, the eighth, the patient complained of pain in the back of the neck and difficulty in eating. Tetanus was suspected and sedatives prescribed. Chloral, grs. xv, sodium bromid, grs. xl every two hours. On the ninth day marked trismus developed, also a slight delirium; temperature 98.2 degrees axilla, and difficulty in swallowing persisted. Positive diagnosis of tetanus made. Tenth day pain in the neck and back very severe, trismus not so marked, difficulty in deglutition increased, although still able to take liquid nourishment. Eleventh and twelfth days, all symptoms intensified, especially the trismus and difficulty in deglutition. Extract of calabar bean in doses of 1 gr. exhibited every two hours. As we had been unable to procure any antitoxins for the first case no attempt was made at this time, but on the twelfth day we accidentally learned from Dr. Evans of the Columbus Laboratory, that a representative of the Institut Pasteur of Paris was in the city and had the antitoxins with him. As the patient's condition was certainly becoming worse, notwithstanding the slow progress of the symptoms, it was determined to try the antitoxins in this case. Thirty c.c. were secured the next day, November 8, and injected in doses of 15 c.c. six hours apart. Immediately following the injection the temperature, which had been normal since the fourth day following the injury, rose to 103.2 degrees, coming down to 100 degrees in six hours. November 8 the patient said he felt better but the pain and spasms in the back of the neck continued and he still had great difficulty in swallowing. This interference with deglutition had so far been the most distressing symptom, though he could manage quite well by taking liquids very slowly, but his hunger and thirst were so great he could with difficulty be controlled. Attempts were made to increase the nourishment and at the same time decrease the feedings by mouth by giving nourishing enemata, but he resisted so strongly that it would have required forcible restraint and on account of the irritation and excitement it was not thought best to resort to such measure. All this time the patient would get out of bed and sit in a chair or go to the lavatory or help himself to a drink whenever he was not watched by the attendant.

November 9, 30 c.c. of antitoxin was administered, the temperature promptly rising to 103.2 degrees and persisting for ten hours, then falling to 99.4 degrees. The patient's condition continued about the same until the next day, when general tonic spasms developed, requiring chloroform anesthesia to control them. During this time the chloral and bromids had been kept up, with one grain doses of extract of calabar bean every two hours. Later in the day delirium and incontinence of urine developed. November 10, another 30 c.c. injected under anesthesia. Temperature rose to 101.4 degrees, falling to 99.4 degrees in eight hours. All medicine and nourishment by mouth had been stopped, as every attempt to swallow produced intense spasms about the mouth and throat, and nourishing enemas containing the sedatives were given when the patient was under an anesthetic. Following each injection of antitoxin there was a noticeable decrease in the frequency of spasms for a period of from twelve to sixteen hours, and during that time the patient rested quietly. The relation of pulse and temperature to the injections is best shown by the accompanying

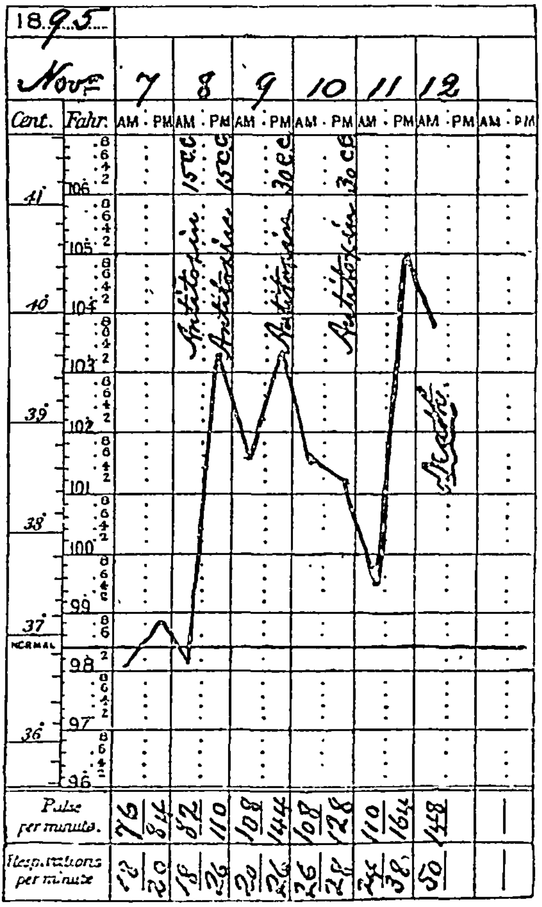

chart. While the pulse followed the temperature curve very closely, it became weaker each day. Four hours after the third injection of antitoxin all spasms ceased, but the patient was unconscious, pulse 136 and weak and general condition bad. Nourishment and stimulants were pushed by enemas and hypodermic injections, but without effect. November 11, twenty four hours after all tetanic spasms had ceased and thirty hours after last injection of antitoxin, the temperature suddenly rose to 105.2 degrees, pulse 164, and the patient became comatose and died six hours later. The autopsy revealed no fracture or hemorrhage that could have caused pressure, and no evidence of [illegible] eit[illegible] ar or cortical, which had been s[illegible] h[illegible] ve co[illegible] plicated the diagnosis. Mi[illegible] b[illegible] e[illegible] inations were not made.

Case 3.—C. E., [illegible]

1896, while coupling cars. Compound fracture left index finger with deep laceration of palmar surface. Also deep laceration of middle finger extending back into the palm. Avulsion of nail and soft part of end of finger nearly crushed off. The hand was thoroughly scrubbed with hot water, soap and brush; foreign bodies, dirt, etc., removed and wounds scrubbed with 1 to 2000 bichlorid solution. The lacerations were sutured, fracture splinted and hand dressed with dry boric acid dressings. The case apparently made good progress until the morning of December 3, when symptoms of tetanus developed with pain in back of the neck and trismus. Did not report to surgeon in attendance, however, until late in the evening. Bromids and chloral given during the night and sent to St. Luke's Hospital December 4, at 9 A.M. At this time the trismus was marked, pain in the neck and back very severe, with some muscular rigidity and beginning convulsions. At 12 M., 10 c.c. of antitoxin injected; at 12:30 P.M., general convulsions and opisthotonos; temperature 100 degrees, pulse 118, respiration 20; 5 P.M., 20 c.c. antitoxin injected; 8:30 P.M., temperature 101.2 degrees; pulse 110; 10:30 P.M., temperature 102.2 degrees, pulse 130, respiration 30; 1 A.M. (December 5), pulse 150; 3 A.M., temperature 102.6 degrees, pulse 128, respiration 40; 3 A.M., temperature 103 degrees; 4 A.M., temperature 105 degrees, pulse 168, respiration 28; 4:20 A.M., dead. From the time of the first injection of antitoxin the convulsions progressively increased in severity, occurring regularly at intervals of about twenty minutes. Sodium bromid, grs. xxx, and chloral, grs. xv, were given per rectum every three hours and inhalations of chloroform frequently, to control the convulsions. The antitoxin injections apparently exerted no influence upon the tetanic symptoms and the circulation weakened rapidly.

In reviewing the published reports of cases of tetanus that have been treated with antitoxic serum, one is at once impressed with two facts: 1, that the mortality rate has been but little influenced by the treatment; and 2, that the relation of the period of incubation to the mortality is practically the same as in cases where serum therapy was not used. In the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION for July, 1896, Kneass makes the mortality of tetanus as heretofore treated about 47 per cent., a result obtained by averaging reports from numerous sources and observers. The same author analyzes a series of sixty-one cases treated with tetanus antitoxin with a mortality of 41 per cent. As regards the influence of the treatment with relation to the incubation period in this same series, he shows the following results:

Period of Incubation.	Deaths.	Recoveries.	Mortality, Per cent.
One to five days.	7	1(?)	87.5
Six to fourteen days. . .	16	25	38
Fifteen days or over. . .	2(?)	10	16.66

He says, as a result of his deductions: "It seems to me that those cases in which the symptoms appear before the sixth day die in spite of any antitoxic treatment, and that those in which the development is delayed beyond the second week would recover without any such treatment." This is almost precisely the opinion that has obtained for the last century regarding the symptomatic treatment of tetanus. In each of the three cases reported above the period of incubation was seven days. The two that were treated with antitoxic serum showed very different results, corresponding closely to the acuteness of the development of the symptoms. In the cephalic case the symptoms developed more slowly and with less intensity and the antitoxin injections seemed to influence the tetanic convulsions for a short time, while they ceased entirely after 90 c.c. had been exhibited, but the circulation gave out either from the effect of toxins or antitoxins. Trevelyan[1] reports a case of head tetanus treated with antitoxins, in which the incubation period was twelve days and the clinical course corresponded very closely to the one reported above, including the reduction of spasms and death from heart failure. Several other cases have been reported, among them those of Mason,[2] Farrant,[3] MacEwan,[4] in which the antitoxin seemed to lessen the frequency or intensity of the convulsive seizures, but the patient died from circulatory depression. Considering that the so-called head tetanus, or tetanus following head injuries, is almost universally described as running a slower and more favorable course than tetanus following wounds of the hands and feet, it would seem that such cases offer the best hope of improvement under antitoxin treatment; yet in the two cases referred to above the results were no better than what might have reasonably been expected from the usual symptomatic treatment, possibly not as good. Some observers report a sudden decrease in the urinary secretion following the exhibition of antitoxin, in some cases amounting to complete suppression. This was very marked in our second case, the amount falling from 30 ounces to less than 12 ounces within the twenty-four hours following the first injection. We have analyzed twenty-six cases that have been reported as having been treated with antitoxic serum within the past two years with the following results: Recoveries twelve, deaths fourteen; total mortality 53.8 per cent. Of those that recovered, the shortest period of incubation was six days; of those that died, the longest period was twelve days. Of twenty-one cases with incubation periods of seven to fourteen days eleven died, or 52.4 per cent. The period that elapsed from the onset of symptoms till treatment with antitoxins was begun, varied in the twenty-six cases from twelve hours to fifteen days and seems to have had little influence upon the result. In seven of the fatal cases antitoxin was administered before the third day, in four of these as early as twenty-four hours. In six of the cases of recovery it was not administered until the seventh day or later, in three later than the thirteenth day. In only four of the above series of twenty-six cases was antitoxin used alone; in the others chloral, bromid, morphia, physostigmin or chloroform were used as well. In comparison with this the series of nine cases reported by Archinard[5] of New Orleans is so unique as to be of interest, particularly as regards the following points: 1. He reports nine *consecutive* cases with two deaths, or *22.2 per cent.;* 2, in the two fatal case the incubation period was *eleven and twelve days,* while in three of the seven successful cases it was *five days or less;* 3, in the seven cases that recovered three received only one injection each of 20 c.c., three had two injections, or 40 c.c., and one was given 60 c.c.; 4, no ill effects were observed from the treatment except a slight rash in a few cases and a little pain at the point of injection. The Institut Pasteur advises the exhibition of much larger doses, 100 c.c. to 200 c.c. after the development of symptoms, and also says that while it is of undoubted value in preventing attacks, both in man and animals, it is of doubtful value after symptoms of tetanus have appeared. Experimentally it has been demonstrated that from 1–400 to 1–100 of the body-weight, 600 c.c. to 150 c.c. for a man, must be used to prevent development of symptoms after inoculation. Doubtless to be of value after the disease has developed even larger doses than that would be necessary. The value of antitetanic serum as a prophylaxis in animals has been proved beyond a doubt by the experiments carried on by veterinarians in France and elsewhere, and following the deductions from the clinical and laboratory observations to date we must conclude that in the treatment of tetanus in man its chief value is doubtless as a prophylactic rather than a therapeutic measure. We believe it deserves a more general use along that line in cases of injury where the wounds are of such a nature that tetanus is to be feared.

In this connection it is of interest to refer to the experience of the Medical Bureau of the World's Columbian Exposition, as illustrating the value of thorough aseptic and antiseptic wound treatment as a prophylaxis of tetanic infection. Dr. Plummer has reported[6] a series of 203 punctured wounds of the foot treated by the Medical Bureau during the construction period of the Exposition *without the development of a single case of tetanus.* Of the 203 cases 202 were nail punctures made, says the author, "in a vast majority of cases by a rusty nail." As to the treatment carried out in these cases the same writer says:

"Although our treatment varied much in different cases, the routine treatment finally agreed upon as being applicable to most cases and followed by the best results, was as follows: 1. Thorough cleansing of the foot with solution of bichlorid of mercury 1-1,000. 2. Trimming the edges of the wound. 3. Swabbing out the wound with a probe lightly covered with cotton and dipped in 95 per cent. solution of carbolic acid. 4. Drainage. 5. Antiseptic dressing. 6. Rest. In the sole of the foot, where the epidermis is very thick, the edges of the wound frequently come together with valve-like accuracy, effectually preventing the escape of anything from the wound, so that, in some cases, it was only after trimming away the edges that the presence of a foreign body was discovered. This procedure also favors drainage. The use of the probe in cleansing these wounds is preferable to syringing, for two reasons: First, it is easy to reach the bottom of the wound with the probe, while it is doubtful in many cases whether this could be done with a solution applied by a syringe; secondly, a small particle of foreign material will often adhere to the cotton and thus be removed."

In several of the cases domestic treatment with various poultices had been tried and followed by cellulitis before the patient presented himself at the Medical Bureau.

Such results certainly justify us in saying that an ounce of clean surgery is worth several pounds of serum therapy in the treatment of tetanus at the present status of our knowledge.

THE PHYSIOLOGY AND THERAPEUTICS OF THE THYROID GLAND AND ITS CONGENERS.

BY H. GIDEON WELLS, Ph.B.
CHICAGO, ILL.

(Awarded the L. C. P. Freer medal, Rush Medical College, 1897.)

From the chemic and pathologic laboratories of Rush Medical College.

(Concluded from page 960.)

Exophthalmic goiter.—In this serious disease we have to consider a condition very different from those previously described, in that they are due to an increased functional activity of the gland. The view that a hyperthyreosis is the underlying cause, is based on several facts, as follows: The symptoms are almost identical with those observed after administration of overdoses of thyroid extract, viz., tachycardia, tremor, headache, prostration and sweating; and a certain degree of exophthalmos has sometimes been observed during thyroid treatment. Exophthalmic goiter has been known to follow an overdose of the extract. The structure of the gland in this disease is almost exactly reproduced in glands stimulated to the highest degree of activity. Halsted, by removing large portions of the thyroid from dogs, has produced a compensatory hypertrophy in the remaining stumps, and he describes the changes as consisting of a branching of the acini with foldings in their walls, so that they consist of alternate recesses and promontories, while at the same time a vacuolation and disappearance of the colloid material occurs and the epithelial cells are changed from low, cuboidal forms to tall, columnar cells which in many places reach entirely across the lumen of the acini and meet in the center. These changes are exactly duplicated by the gland in Basedow's disease. And further, if this condition is due to a hyperthyreosis we would expect the administration of thyroid extract to aggravate the symptoms, and this is exactly what does occur. Thyroid preparations have been tried in hundreds of cases by reliable observers, and the great majority of them agree that the patient becomes much worse under this treatment, and is relieved on its cessation.

The writer has analyzed the thyroid in one case of exophthalmic goiter in which the gland weighed 17 grams, containing in each gram 0.3 mg. of iodin, a total amount of 5.1 mg. This small proportion is readily explained by the microscope, for, as stated above, the colloid probably vacuolates and disappears as rapidly as formed, so that none is stored up in the acini. We must therefore conclude that the symptoms are due to a rapid production of colloid by the hyperactive epithelium, the product apparently being more fluid than normal, and discharging at once into the system by the lymphatics.

With all these facts to oppose them the theories of a purely nervous origin of exophthalmic goiter in the cervical ganglia or the restiform bodies have lost much of their support, although some authorities still uphold them, and a few surgeons have reported good results following the removal of the cervical sympathetic ganglia. Whatever the cause of Basedow's disease may be, it is pre-eminently the condition in which thyroid therapy is contra-indicated.

These four diseases above mentioned include all those due to evident changes in the thyroid itself, and are naturally the conditions in which this form of treatment was first suggested. Were they the only conditions in which it is of use the thyroid extract would have little market in this country, where goiter, cretinism and myxedema are so rare; but there have been a great number of other uses to which it has been applied, and its success in one of them would seem to be sufficient to place it in the hands of every physician; that disease is obesity.

Obesity.—During the treatment of the diseases above described it was generally noticed that the patient, especially if stout, began to lose weight, and this while gaining in strength and vigor. In fact loss of weight is one of the most prominent symptoms observed in cretins when first put upon thyroid treatment. These observations suggested the experiment of exhibiting thyroid preparations to patients with troublesome obesity, and the most happy results were obtained. Even without change of diet there is a marked loss of weight at first, frequently one pound a day for three weeks or so, and when combined with the usual dieting methods a most pleasing reduction in weight is obtained. This loss of weight is also produced without injury to the body, or loss of strength and health. The fat is removed as carbon dioxid and water, while there is comparatively little loss of the nitrogen, containing tissues, making it an ideal remedy. The reliability of the method is shown by a series of 145 cases, collected by Cabot, in all but six of which there was some improvement. The improvement is not permanent, except in a few cases, but if the patient adhere to a system of dietetics and exercise, such as is ordinarily used, the ground gained by the thyroid extract is held. In all probability the benefits of this treatment are due to the increased metabolism in the tissues, producing the same results as vigorous and general exercise, *i. e.*, a burning up of the superfluous carbonaceous materials in the body. It can not be stated positively that obesity is or is not due to any diminution in the activity of the thyroid from lack of investigation on this point, but it has often been noticed that the thyroid glands of obese people are smaller than normal, red and soft. Study of the structure and iodin content of such cases may throw some light on the question.

Nervous diseases.—Because of the awakening of the intellect of the cretin, the removal of the apathetic condition of the myxedematous patient, and the nervous symptoms observed similarly in over dosing with the thyroid extract and in exophthalmic goiter, the thyroid treatment has been tried in conditions referable to both the peripheral and central nervous systems.

In insanity the results seem to be variable. Bruce tried the treatment in the Royal Edinburgh Asylum in cases not amenable to ordinary methods, and obtained many gratifying results in patients threatening to pass into confirmed dementia, or who had been tuporous for long periods. He considers it of value a cerebral stimulant where the higher cortical cells anergic after acute attacks of acute insanity. On the other hand the majority of observers report no improvement whatever in the mental conditions, and consider it dangerous in acute mania and melancholia. A more extended trial along these lines is needed before the thyroid therapy can be absolutely condemned, for it seems very reasonable that its effects on metabolism may in some cases improve the condition of the higher cerebral centers.

The writer has had occasion to examine, chemically, the thyroid from a case in which mental development was arrested, in a female, at about two years of age. The patient lost every particle of reason, and had been fed and cared for by attendants until she died at the age of 23 years. She had frequent convulsions during all this time. The thyroid was rather large, nearly encircling the trachea, and weighed when dry 11.62 grams. Each gram contained but 0.532 mg. of iodin, the total amount being 6.16 mg. While the total amount is small, and the proportion very low, yet an isolated case like this can not be considered an indication of the usual condition.

Since tetany has been observed to follow thyroidectomy, both in man and animals, the use of the gland in cases of the idiopathic disease is rational, and the clinical results seem to justify it, Levy-Dorn, Gottstein, Bramwell and others have reported very favorable results, some of the cases having been of long-standing.

Chorea has been treated with some success by the thyroid extract. Wolfstein reports a case with excellent result, in which the use of the thyroid was based upon its effect on metabolism, its use in tetany, and its diuretic action.

Lepin has reported two cases of progressive myopathy, in which, after electricity the usual treatment were found unavailing, the thyroid gland was given with the result that in a short time muscular vigor was greatly increased without change in their size.

Stieglitz, in a case of hemiatrophy of the face with clonic convulsions of the temporal and masseter muscles, produced a marked improvement by administration of thyroid extract, but the relief was only temporary.

Skin diseases.—The use of the thyroid in this class of cases was suggested by the effects on the skin in myxedema. It has been tried most in psoriasis, with varying results. Of 154 cases collected by Cabot sixty-three were reported as improved, fifty-three as unimproved and twenty-two as worse. Some of the cures, however, were in very obstinate cases. Similar results are reported in eczema, acne rosacea, icthyosis and xeroderma. Therefore it would hardly seem that the thyroid therapy was to be applied promiscuously, at least, in dermatologic affections.

Scleroderma, however, seems to offer a more favorable field. Grünfeld and Stieglitz have each reported cases in which a permanent improvement was produced by this treatment, and the writer has had the opportunity to study, postmortem, a case of the diffuse form of this disease in a woman, 51 years of age, in whom the disease had existed for about one year. The thyroid gland was found to be atrophic, weighing but 14 grams when fresh. Microscopically it was found to consist of groups of acini, collected into lobules, and in the lumen of which there was little or no material. In occasional areas, on the other hand, a few vesicles had become filled with colloid until their walls had ruptured and large cysts formed. There was a general increase in the connective tissue, and the vessels of the gland had undergone a proliferation of the intima and calcification. The dry gland weighed only 3.23 grams, and in each gram there was but 0.91 mg. of iodin, so that the total amount reached 2.94 mg. but little more than one-fourth of the normal quantity. In addition to this the hypophysis was hypertrophied, weighing 0.7 gram, and microscopically it was found that many of the alveoli were dilated by a colloid secretion and in their walls were an unusual number of eosinophile cells. If these changes are constant in scleroderma they point strongly to a thyroid origin for the disease.

In lupus, Bramwell and Abraham have had favorable results, obtaining an improvement in all of their cases, but no cures.

Miscellaneous.—Morin first tried thyroid extract in pulmonary tuberculosis, basing the treatment on the fact that in phthisis the thyroid is usually atrophied, that in goitrous districts the people with enlarged thyroids rarely acquire tuberculosis, and that phthisis has been observed to improve after the patient acquired goiter. The results in phthisis have indicated a general temporary improvement, such as generally follows any new form of treatment in this disease. If there is any specific action of thyroiodin on tuberculosis, it seems difficult to account for the not infrequent occurrence of tubercular areas in the thyroid gland.

In syphilis this treatment has also been tried, and its reported success in two cases of a very malignant form, acquired in India by British soldiers, created considerable interest. Since the active principle is an iodin compound, the application to syphilis seems reasonable. But it seems very strange that when iodin is a specific in syphilis we should have gumma develop in the thyroid gland which contains so much of this element, yet this sometimes happens.

Because of its effects on cretins, and its influence on metabolism, the thyroid extract has been used in many cases of stunted growth in children, and in nearly all the cases increase in height has followed. In the same way it has been administered in rickets with some reports of improvement.

It has also been used and reported as efficient in removing scars, deformed finger nails, keloids, fibroids, including myo-fibroma of the uterus. In fact, to enumerate all the conditions to which it has been applied, with at least imagined success, would almost be to give the entire list of known pathologic conditions.

Summary.—Put in compact form, the sum total of our knowledge of the thyroid gland amounts to the following, according to the results of the latest investigations:

The thyroid gland is an organ of very variable size and shape, reaching its highest degree of development at about adult life, and decreasing with old age.

It is capable of great hypertrophy, but probably is not capable of more than a slight degree of regeneration.

Its secretion is a colloid material, which is discharged into the general blood current by way of the lymphatics.

The colloid material contains the active material of the gland, which is a complex but very stable body, called "thyroiodin," which contains about 10 per cent. of iodin.

This substance either acts as an antitoxin to the products causing auto-intoxication, or furnishes some substance necessary to tissue metabolism.

Thyroiodin is necessary to the animal economy, absence of it in adults producing myxedema; in the new-born, cretinism.

The amount of iodin in the thyroid glands of the inhabitants of any given district varies inversely with the prevalence of goiter in that district.

Thyroid glands of residents of Chicago contain fully four times as much iodin as do glands in the goitrous districts of Germany

It is probable that glands from the Atlantic coast contain about the same amount of iodin as do the Chicago glands.

Simple parenchymatous goiters contain about the same total amount of iodin as normal glands, but the proportional amount is much smaller. Probably colloid goiters contain the same proportional amount, with a very much higher total.

The amount of iodin in the glands of children, from a mere trace at birth, steadily increase until adult years. It then decreases, and in old people again becomes very small.

Therapeutically the thyroid extract is a specific in cretinism and myxedema.

In simple goiter and in obesity the majority of cases are improved or cured.

It seems to have some value in tetany, scleroderma and arrested growth.

The value in psoriasis and other skin diseases, tuberculosis, insanity, rickets, etc., is doubtful.

It is contra-indicated in exopthalmic goiter, heart lesions, albuminuria and glycosuria. The dose should never be so large as to produce symptoms.

THE THYMUS AND HYPOPHYSIS.

In a study of the thyroid gland one's attention is necessarily called to two other organs in very close relation, both by the manner of development and the general obscurity which surrounds their function. They are the thymus gland, and the hypophysis or pituitary body.

The Thymus.—This gland is developed from the entire third visceral cleft and from a part of the fourth cleft, the remainder of which goes to form the lateral lobes of the thyroid. This common origin explains the frequence of thymus rests in the substance of the thyroid gland. From the terminal end of the cleft is formed a tube lined with epithelium, which grows downward and unites with its fellow in front of the trachea, and then becomes ramified. At this stage the thymus is a purely epithelial organ, like the thyroid, but it soon becomes invaded by a growth of lymphoid tissue which forms in lobules about the epithelial tubules, the latter undergoing atrophy until only a small concentric group of flattened cells is left in the center of the lobules. The entire gland increases in size slightly up to the second year, when it weighs between 5 and 15 grams, and then gradually disappears until about puberty, when it is replaced by fat and connective tissue. In some cases, however, the thymus is persistent until adult years.

The thymus is structurally part of the lymphatic system, and is affected in the diseases involving the lymphatic system as a whole, such as leukemia and pseudo-leukemia. With the rest of these organs it also seems to be engaged in the formation of both red and colorless corpuscles. Watney describes the thymus as containing hemoglobin in cysts and in cells located near to or forming part of the concentric bodies. He believes that this hemoglobin is collected into masses resembling red corpuscles, and which pass out through the lymphatics into the blood vessels where they become red corpuscles. There are said to be more colorless corpuscles in the veins and lymphatics of the thymus than in the arteries and lymphatics of the neck. The thymus also contains many extractives similar to those of the spleen, and a globulin has been derived from it that is capable of producing extensive intra-vascular clotting.

In addition to these functions, common to other lymphatic glands, the thymus serves an important part in the economy of hybernating animals. In them it remains throughout life, and every fall becomes the seat of a great deposition of fat which by spring has been entirely used up, the gland apparently acting as a store-house for the accumulation of fat to meet the needs of the animal during its dormant condition.

From its structure there would seem to be no relation between this gland and the thyroid, yet Baumann has found that the thymus contains iodin, which he believes is in the form of thyro-iodin. The writer has analyzed the thymus glands of four children. In one from a four months old child, and in one from a still-born infant, slight traces of iodin could be detected. In the other two, which were both from still-born infants, no traces whatever could be detected, even when three grams of the dried grands were examined at one time.

Another thing that points to some relation between the thyroid and the thymus is the frequency of persistence and hypertrophy of the latter in exopthalmic goiter. Prof. Hektoen has reported a case illustrating this fact, the goiter weighing 100 grams, and the thymus 60 grams.

The use of the thymus extract in exophthalmic goiter has led Owen to believe that the thymus may have an inhibitory action on the thyroid secretion, supposing Basedow's disease to be a hyper-active condition of the latter. In support of this idea he cites the fact that exophthalmic goiter rarely occurs in children before the disappearance of the thymus, and also that the thyroid produces emaciation, while in the hybernating animals the thymus prevents it. None of the theories advanced to explain the function of this organ fully meet all the conditions, so that most authors are content to say that it provides some substance necessary for the development of the young, and that it atrophies on the cessation of the need of this material.

The thymus extract has been used chiefly in exopthalmic goiter, and has there met some success. Of forty-three cases collected by the writer, from the current literature, improvement was observed in thirty-one, varying from apparent cure to slight diminution of the symptoms. Todd in one case obtained a reduction in the pulse rate from 156 to 72 in three weeks, with great improvement in three other cases. On the other hand Dreschfeld obtained no results in three cases. Mackenzie, who has treated twenty cases in this manner, does not believe that the thymus has any great therapeutic activity. He thinks that its benefits are limited to an improvement in the general condition, without specific effect on the heart, goiter, or exophthalmos.

In the Breslau clinic the thymus preparations have been used in simple goiter with much success. Thirty cases were treated in this way, of which twenty were successful, the goiter not only diminishing in size but the subjective symptoms also disappeared. In some of these cases the thyroid extract had been used unavailingly. The favorable cases were all of pure diffuse hyperplasia. Ten to thirty grams of fresh sheep's thymus was given three times weekly. In other cases the thymus tablets, made in the same manner as those from the thyroid, were used. Small doses seem to give fully as good results as do the large.

The hypophysis.—This organ bears a still closer relation to the thyroid, not only in its development and structure, but in its clinical and pathologic manifestations. In origin it corresponds to the median portion of the thyroid, being developed from a diverticulum of the buccal epiblast from the posterior wall of the pharynx. This becomes flask-shaped and partly enfolds the end of the infundibulum developed from the second cerebral vesicle, the nervous portion becoming the posterior lobe and the epiblastic diverticulum forming the anterior lobe of the mature gland. The epithelial portion becomes divided up into alveoli, which in the normal hypophysis are for the most part empty, but occasionally one can be found to contain a small amount of a material apparently identical with the colloid substance of the thyroid gland. Around the alveoli is a network of capillaries, with little connective tissue stroma.

Our knowledge of the function of this gland is very limited. Experimental removal has so far given contradictory results, a muscular twitching having sometimes been produced. Administration of the gland to man and the lower animals, according to Mariet and Bosc, causes a slight and transient elevation of temperature, gastro-intestinal disturbances and a temporary albuminuria. It seems to have but a slight degree of toxicity. The same authors report the results of the administration of the pituitary body in twenty-one cases of epilepsy, from which they concluded that it was powerless to prevent or diminish the number of attacks, and they also observed a quite constant delirium three or four days after it was administered.

There can be no doubt that the hypophysis is closely related to, if not the direct cause of, the condition known as acromegalia, which is characterized by an abnormal growth of some one part of the body, most commonly the extremities or face. In practically every case of this disease the gland is found to be enlarged, sometimes to the size of a hen's egg. It is also probable that many cases of giantism are traceable to this little organ, since many of the famous giants have been acromegalic, while the skulls of giants show in many instances enormous enlargement of the sella turcica.

This suggests that the hypophysis has a trophic function, a hyper-activity of the gland therefore producing an increased growth, either local or general. In support of this theory it is stated that in the older vertebrates, and in some of the low forms now in existence, the diverticulum forming the organ does not become obliterated but remains as a tube, which is continuous with the canal in the infundibulum, and so with the ventricles of the brain and the central canal of the spinal cord. This tube is lined with ciliated epithelium, and Andriezen has observed that in animals particles of pigment pass from the buccal cavity through this canal and down the entire length of the spinal cord. In this case the hypophysis surrounds this nutritional canal, and presumably excretes into it certain substances from its glandular portion, while the nervous lobe regulates the quantity and quality of the material passing through it. It is supposed that while in the higher forms the gland loses its connection with the alimentary canal, it still retains its control over the nutrition of the central nervous system, and so exercises a trophic influence over the rest of the body. This history shows another resemblance to the thyroid, which is also originally connected to the alimentary canal by a duct, which in later life becomes obliterated.

The connection between these organs is certainly a very close one, not only in their anatomic and embryonic relations, but also in their pathologic changes, when they seem to attempt to compensate one for the other, and also to be affected by similar conditions. For example, in animals that have their thyroids extirpated there is almost always an hypertrophy of the pituitary body, and the same condition has been observed in this organ in people dying with myxedema. In the case of scleroderma described previously, where the thyroid was greatly atrophied the hypophysis weighed 0.7 gram, the average weight of twenty-one normal glands collected at the Cook County hospital being but 0.1 gram. This increased size seemed to be due to the fact that the majority of the alveoli of the hypophysis contained colloid, in some the quantity being so large as to convert them into true vesicles, while in a normal gland the colloid material is generally found in only a few alveoli in each section, and then in extremely small quantities. The walls of the alveoli also contained an unusually large number of eosinophile cells. It would seem that in this case the hypophysis had undergone a true compensatory hypertrophy secondary to the atrophy of the thyroid. Conversely in the great majority of cases of acromegalia the thyroid has been found to be altered, sometimes goitrous and sometimes atrophic.

Fourteen normal pituitary glands were analyzed by the writer, and found to contain iodin in no inconsiderable amounts. On account of the small size of the individual glands they were analyzed together. The total weight when dried was but 1.225 grams. Altogether they contained 0.05 mg. of iodin, an average amount of 0.0036 mg. for each gland. The proportion of iodin is much smaller here than in the thyroid, about one to fifty, and suggests that in the hypophysis also the iodin exists in the colloid material, as the colloid there forms but a correspondingly small proportion of the total bulk of the organ, and if that is the case the iodin probably exists in the form of thyroiodin.

Whether the gland has any other effects than can be attributed to the iodin compound it contains, can not be said. Schaefer has found that injections of pituitary extract into dogs causes a marked increase in blood pressure with augmentation of the force of the heart beat. This is just the opposite from the effect he obtained with thyroid extracts, so he believes that this experiment negatives the theory of identity of function of these two organs.

Therapeutically the pituitary gland has so far been a failure, both in nervous and nutritional disorders. It has been tried in acromegalia, but without result. If acromegalia is due to hypertrophy of this organ, one would not be justified in using pituitary extract, any more than he would use thyroid extract in exophthalmic goiter, since theoretically, at least, this treatment would serve to augment the symptoms of the disease.

ADDENDUM.

Since this article has been in the hands of the publisher, results have been obtained from the analysis of six thyroid glands received from Baltimore and an equal number from Montreal. The Montreal glands averaged 4.49 grams in weight when dry, each gram containing an average of 2.4 mgr. of iodin, the total amount per gland being 10.77 mgr. The weight of the Baltimore glands averaged 5.41 grams, each gram containing 2.36 mgr. of iodin, an average of 12.76 mgr. for each gland. These results differ but little from those obtained from the series of glands from Boston and New York, and seem to indicate that the iodin content of thyroid glands of residents of different parts of the country is practically the same.

An Interesting Study of the movements of the arms in walking was presented at Moscow by Dupré, who traces them to an ancestral origin, relics of a past age when man walked on all fours. They are more pronounced in children and in the less developed cerebrally, than in adults.

HOLOCAIN VS. COCAIN.

BY F. C. HOTZ, M.D.
CHICAGO.

Early in August I received from the druggists Gale & Blocki, a 1 per cent. solution of holocain for testing its anesthetizing virtues. I first tried it on a few normal eyes and on eyes with foreign bodies in the cornea, with the following results: The instillation always caused more or less smarting and burning, which however lasted but about half a minute; it also produced considerable redness of the conjunctiva (palpebral and ocular), which persisted during the whole period of anesthesia. Within one and one-half to two minutes complete anesthesia of the cornea was noted; after six minutes the sensibility of the cornea began to return, but a second instillation prolonged the anesthesia for another five minutes; and if then another drop was instilled the anesthesia could again be continued. It would seem then that the anesthetic effect of holocain can be kept up indefinitely by repeating the instillation every five minutes. With cocain this can not be done; at least I have noticed that if the eye is coming out of the cocain anesthesia, repeated instillations do not restore the anesthesia; on the contrary, I have often found the eye becoming more sensitive the more cocain was used. Holocain does not contract the conjunctival blood vessels and therefore causes neither bleaching of the eye nor lessening of the lacrymal secretion nor drying of the corneal epithelium. It does not dilate the pupil and has no effect on the accommodation. On account of these qualities one would naturally feel inclined to use this new anesthetic in preference of cocain, in all operations on the eye. But a series of comparative tests of the efficiency of the two remedies seemed to show that the anesthetizing effect of cocain (2 per cent.) is more thorough and penetrating than that of holocain (1 per cent.). I had, for instance, two patients with corneal ulcers which required the repeated application of the electro-cautery. I made one application under holocain anesthesia and the next time cauterized the same eye under cocain. Both patients, who thought cocain was used on both occasions, said the first cauterization was decidedly painful, while they did not feel the second one at all. I performed an advancement of the externus on the right eye under holocain and on the left eye of the same patient under cocain; complete anesthesia of the conjunctiva in both eyes; but the cutting and suturing of the tendon was decidedly painful in the holocainized eye, while scarcely felt in the cocainized eye.

The most telling illustration of the difference in their penetrating effect was furnished by a case of subconjunctival injections of cyanid of mercury. Several injections had previously been made under cocain and the pain following the injections was moderate and never lasted over five to ten minutes. The next injection was made under holocain and caused the most violent pain, which after twenty minutes showed no sign of letting up in intensity; I then instilled cocain and within five minutes the patient was free from pain. One week later this experiment was repeated with the same result.

All these observations seem to show that the effect of holocain is very quick, but superficial: it is therefore a very useful local anesthetic for the removal of foreign bodies from the cornea, and for operations upon the conjunctiva; but for deeper operations, and especially for those which involve the opening of the globe (iridectomy and cataract extraction), I regard cocain as the more reliable anesthetic.

SURGERY ONE HUNDRED YEARS AGO.

AN HISTORICAL STUDY

BY DR. GEORGE FISCHER.

DEDICATED TO THE GERMAN SURGICAL ASSOCIATION.

TRANSLATED FOR THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION
BY CARL H. VON KLEIN, A.M., M.D.

XVI.—DISEASES OF THE BLOOD VESSELS, NERVES AND SKIN. NEOPLASMS.

(*Continued from page 965.*)

Tetanus was not unknown to the German military physicians. Bilguer relates that after the battle of Prague (1757), several thousands with slight wounds died in the field hospitals of so-called "dog-cramp," in spite of careful treatment by Cothenius, Schmucker and others; and the same was true after the battle of Liegnitz. Later in the war he saw the cramp more rarely. The bad hospital air was recognized as the cause of tetanus (in which A. de Haën had already measured the higher temperatures) and Theden recommended ventilation for the improvement of the air, as a prophylactic remedy for tetanus, although a draft often induced it. Certain ligatures were also condemned as a cause of tetanus, especially in castration (Theden, Plenk and Morand). Bilguer attached great importance to local treatment, and enlarged gunshot wounds in length and depth in order to bring about widening. Plenk and Siebold amputated with success, for which method Larrey in particular later entered the lists. In internal treatment opium, especially recommended by Petit and Bilguer, stood in high repute, and large doses were given without hesitation; Windsor gave 25 drops of laudanum every three hours. Charles White gave 317 grains of poppy juice within five weeks with success. Others, on the contrary, saw no use whatever in opium, and since it was said principally to effect relaxation, they preferred quinia and wine (Rush). Charles White advocated warm baths; cold water, which the ancients applied, was endorsed by Wright in Jamaica, who poured a few pailfuls over the patients every few hours, and also by Curne, who threw his patients into water and immersed them several times. J. Hunter declared in his lectures that he would proceed with the disease according to Zamblé and have himself put into an ice-house.

Parry of Bath first introduced therapeutically the *compression of the carotid* for certain nervous diseases (1789). Rufus of Ephesus and Columbus knew this method. Parry would in this way relieve delirium, dizziness and convulsions, but noticed a return of the symptoms as soon as the pressure ceased. Severe headache, for which Felix Würtz had one of the art. temporales severed, and had "given praise, honor and thanks to God Almighty" for the cessation of the pain, Parry had relieved immediately by compression of the carotid or the temporal. He allayed pain in the feet by compression of the art. poplitea, pain from panaritium by a pressure upon both sides of the fingers. Compression of the carotid was also recommended for *facial pains*. When Fothergill first accurately described this ill (1776), already known to the ancients, to which the Versailles surgeon André gave the name *tic douloureux* (1753), he regarded hemlock as the only alleviating remedy; hence he was obliged to believe that the evil arose from "an occult cancer-like acridity." Later he located the causes of the pain in the stomach, and gave purgatives and emetics. Galen had already recommended severing the N. infraorbitalis; Albin performed this operation, but a cure ensued only after a second intersection, while Thouret maintained (1782) that in most cases the operation had been without any result whatever.

Among the surgical diseases of the skin the terribly extensive picture of *ulcers* is most conspicuous. On no theme in surgery were so many variations composed as upon this; every writer had his own classification. Pus and ichor were considered as the actually destructive element, and therefore they defined ulcer as a dissolution of a combination, from which results pus and ichor or decomposed blood (B. Bell). It was said that an increased activity of the lymph vessels causes a waste of substance (J. Hunter). We give Richter's classification, and construct a plan out of his treatise in order to save tedious descriptions.

I.—VARIOUS CAUSES.

a. Internal causes.—1. Venereal (plain syphilis, disguised syphilis, consequences of badly treated gonorrhea); 2. Scurvy; 3. Scrofula; 4. Gout; 5. Obstructed menstruation; 6. Hemorrhage of the hemorrhoidal vein; 7. Absorbed skin eruptions; 8. Diseased urination; 9. Suppressed perspiration; 10. Irritation in the intestines, most frequently bilious or atrabilious; 11. Resulting from smallpox; 12. Bad condition of the fluids.

b. External causes.—1. Misuse of salves; 2. Foreign bodies (diseased bones); 3. Sharp irritating agents.

II.—VARYING CONDITIONS OF THE SOLID PARTS.

1. Simply unclean; 2. Callous; 3. Fungus; 4. Inflammatory; 5. Painful; 6. Varicose; 7. Edematous; 8. Scirrhous.

III.—VARYING CONDITION OF THE ICHOR.

1. Corrosive; 2. Putrid; 3. Rancid; 4. Humid; 5. Dry.

IV.—VARIATIONS IN AGE AND FORM.

1. Fresh; 2. Old; 3. Open; 4. Fistulæ. Supplementary (Complicated ulcers, salt rheum).

As to treatment there was a mass of obscurity and prejudice. B. Bell deserves the credit of introducing clear principles. It was necessary to remove the cause; if this was unknown one was obliged to address himself to the condition of the solid parts and the ichor. If this also was unavailing, then empiric means were resorted to. Naturally there were ulcers which they could not cure at all. The list of medicines in use was enormously large; those which were not swallowed were spread on. Disregarding the antidyscrasia remedies, mercury for syphilis, quinia, antimony, hemlock and cold baths for scrofula, etc., artificial warmth belonged especially to the empiric methods. It was applied in the shape of a warm bandage, glowing coals were held in the vicinity of the ulcer (Faure), or the sun's rays were caught by a burning glass and concentrated upon it (La Peyre). The other chief empiric agents were mercury, antimony ore, nitrate of silver, hemlock, belladonna, quinia, poppy juice, water fennel, chenopodium, burdock and pulverized zinc-white. As a forerunner of the present Hoff's malt extract now become well known through advertisements, a malt drink enjoyed a high place among the antiscorbutic remedies, and was also recommended for cancer (1771). They put six ounces of barley malt into a quart of water and boil it a quarter of an hour with some fennel seed and licorice, and let it stand four hours in a closed vessel, in a warm place. The patients drank two or three pounds of this daily. In external therapeutics the surgeons clung principally to the application of salves and envelopment. They finally became aware of the infinite abuse of salves. The Académie de chirurgie (1772) published a prize essay on the dangerous application of these. Faure answered this by stating that he repudiated salves and plasters entirely and B. Bell ascribed to salves only the advantage that they prevented the adhesion of the lint. These maxims were taken up by the good surgeons of all nations. That was an extraordinary advancement in the treatment of the ulcer; one needs to read only once the long winded directions for plasters composed of from ten to twenty ingredients, which Purmann and his contemporaries applied to ulcers. The value of envelopment was first recognized in the case of varicose ulcers and was later appreciated in all edematous and obstinate ulcers. As to varicose ulcers, views were divided according to whether they were considered a dyscrasic or a local affection. The ancients cut the varices out, but were already aware that this was often of no avail (Ætius and Paul of Ægina); later the double bandage and evacuation by puncture was practiced (Fabr. of Aquapendente). Compression for varicose vein was known to the Arabians; Avicenna described a compression bandage from the lower part of the leg to the knee. But they did not venture to use compression if ulcers also were present besides the varicose vein. Fabr. von Hilden and Scultet first applied a compression bandage to the ulcers. Subsequent time forgot these methods, until Theden won the distinction of snatching them from oblivion (1771). Else, Bell, Richter and others imitated him. In France, Desault, who highly prized compression in general as one of the best resorptive methods, adopted this bandage and attained the best results in varicose as well as all callous ulcers. He thought that for a relapse laced stockings of dogskin were the best, an old remedy already applied by Fabr. of Aquapendente, Wiseman and Scultet. To this treatment was added the method of the Oxford professor, Rowley, who discarded rest and the horizontal position along with the internal use of saltpetre, and had the patient walk about considerably (1771). Eight years later this method was still entirely unknown in London. Baynton improved the compression bandage by his well-known envelopment with adhesive plaster (1797). When old and large varicose ulcers gave much pain and bled often and profusely, a ligature was applied above and below the ulcers (Richter); and the vena saphena was constricted above the knee-joint (E. Homer). It is of no interest to follow farther the therapeutics of ulcers. But we will mention that the gastric juice was announced from Geneva as an excellent means to allay stench and pains (1787), and we will close with the homeopath, Samuel Hahnemann. He wrote instructions for the fundamental cure of old injuries and putrid sores (1784). The closing words characterize his work: "Who has had the opportunity to make so many observations as I: who allows himself to be so influenced and absorbed by the well being of his neighbors as I feel that I am; who hates so much the prejudice and the partiality for the old and the new, or in general the regard for any great name, and so earnestly strives to think and act for [illegible] in mys[illegible] who can with me see [illegible] of own industry, succe[illegible] since they almost [illegible] sicians using different treatment?" Richter's criticism left nothing to be said; unintelligible, pompous, vague, impractical rubbish!

This surgeon considered the *furuncle* as a swelling which arises from stagnant, thickened humors, in part from coagulated blood; its thrombus he regarded as a cyst of cellular tissue or perhaps a cutaneous gland. He considered the *carbuncle* as a malignant swelling arising from corrupt matter extracted from the blood, and he recommended an early incision. *Erysipelas*, either idiopathic or only a symptom, was an inflammation mostly arising from biliary acridity or suppressed perspiration. Gregory and J. Hunter had already taught that any specially poisonous matter has such an effect. It might be combined with inflammatory (erys. phlegmonodes) or putrid fevers (erys. malignum). Special kinds were the laminated erysipelas, with which the so-called girdle or St. Anthony's fire was included, and a habitual or chronic erysipelas which often proceeds from affections of the liver. The treatment consisted in diaphoretic remedies, purgatives and emetics; only in serious cases did they resort to the lance. As external remedies, which were in general regarded as injurious, they permitted only little bags of chamomile and elder to keep the part moderately warm and protect it from the air. They allayed severe pain with a piece of flannel which was moistened with elder flower tea. In suppressed erysipelas, bleeding, mustard plasters, blisters and emetics were necessary. These were the principles of Desault and Richter.

Burns were divided into different degrees, of which Heister, Richter and John Hunter accepted four, which covered the ground pretty well. Heister distinguished rednesss, blister, superficial suppuration and scar formation; Richter, mild redness, redness with swelling, severe pain and fever, blister and mortification; J. Hunter, superficial inflammation, deeper inflammation, skin eschar and deep charring. In the two first degrees of Richter, brandy and oil of turpentine were applied (J.Bell), and Theden's arquebusade-water; in cases of severe pain emollient pulps and oils, especially linseed oil. The blisters were carefully opened and covered with linseed-oil, lead or lime-water. In case of *freezing* the rule was to warm the part very gradually by rubbing it with snow or ice-water. Chilblains were most effectively treated in the same manner, for which there was besides a mass of balsams, oils and spirits. The different kinds of *panaritium* were classified then as now; the pus lay either just under the epidermis or the nails, or the inflammation had its seat in the cellular tissue, in the sheath of the tendons or in the periosteum. Richter added, besides, a dry felon in which the soft parts were naturally constituted, but the bone had been transformed into fat. The methods for dispersion were bleeding, leeches (Schmucker), envelopment of the fingers upward to the arm (Theden), immersing the fingers in hot water (Platner), in ice-cold water (according to Aëtius), etc. Richter gave the best advice when, if the conditions had not improved by the fourth day, he made an incision whether the pus had formed or not: for great relief always followed even if only blood came. In inflammation of the periosteum he early made an incision quite to the bone in order to induce a relaxation; in inflammations below the nail he scraped it quite thin with a piece of glass and cut out the point of the nail with the bistoury. An inadequate treatment of panaritia even led to amputation of the fingers, as one frequently saw in Paris at the end of the century.

Warts were supposed to arise, for the most part from local, sometimes from internal causes (syphilis, and undue use of milk-foods for children). Among the local remedies were spirits of sal ammoniac, butter of antimony, spanish fly plaster, compression, binding, and the sticking of a red-hot needle into the root of the wart. Corrosives and extirpation demanded great precaution. It is not without interest to notice how the common *corn* was found worthy of study by the two most celebrated Dutchmen. Albin investigated it anatomically (1754), and found that the hardness consists entirely of epidermis, that after slight maceration it can be stripped off, and underneath the skin-papillæ are atrophic while they turgesce strongly in the vicinity. Camper gave the best remedy for the disease where the shoe pinched. We will insert his interesting essay here:

> *What is the best shoe?* P. Camper answered this question (1781), when his pupils declared that the material for dissertations was exhausted. He wished to show them that even the most unimportant subject can become interesting. "It was thought that I would never venture to publish an essay under my name. I condescended to it and wrote." Posidonius has asserted that the shoemaker's art was very obviously devised and perfected by the philosophers. Anatomy and mathematics is the basis of their work. The work of the cobblers of that time could only serve to deform the toes and to induce corns; even the most skilful shoemakers took the measure incorrectly. The ladies of fashion wore very high, pointed heels, which, in order to make the foot appear smaller, were placed as far as possible under the back of the foot. The heel was hollowed before and behind, and ended in more or less of a point, just as do the boots of the present women. Camper said that the high heels not only made the ladies walk upon the points of the feet badly and never comfortably outside of their own houses and the well-paved streets; that in consequence of the insecure footing, in the case of girls, the spine became bent insomuch that it caused difficult parturition, because in severe curvature of the spine the head of the child was squeezed. It was customary in Dutch villages, but not in the cities, to make a special last for each foot, as the same shoe could never fit both feet well. Camper gave the following rules: 1. The shoemaker must first measure the foot when flat and then when bent in order to determine the length of the sole. 2. A special last is necessary for each foot. 3. The breadth of the foot must be measured with a curved compass. Most shoemakers fail in this and make the soles too small because they think that the upper leather will stretch sufficiently. 4. The end of the shoe must be round in order to give more room to the toes. 5. The point should be bent somewhat upward in order to pass more readily over uneven stones. 6. The height of the heel must be regulated according to the roughness of the streets and it must be placed so far under the heel of the foot that the center of gravity rests upon it. 7. The buckle should touch the cuneiform bones. Camper demanded soft uppers and discarded cork soles because they were not yielding and did not absorb moisture. Among the ailments which were superinduced by bad shoemaking he submitted the following: callous cuticle, pains at the joint of the great toe caused by too small soles, warts under the nail of the great toe, caused by too short a sole and too stiff leather, and also corns.

That a too narrow shoe was the chief cause of corns was as well known at that time as now. They sought to relieve the presence by a plaster made of several strips of linen with a hole in the middle the size of the corn. Richter promised sure cure in a short time if a resolvent salve or a volatile liniment were rubbed on the corn several times a day and a warm foot bath taken for half an hour morning and evening, the corn being vigorously rubbed with soap. Then the softened corn should be pared off with a dull knife. This treatment repeated daily should accomplish a complete cure in one or two weeks. The number of other remedies was large: Soap plaster, mercury plaster, fat, and an infallible plaster of gummi ammoniacum with yellow wax (ana 2 ounces) and verdigris (6 drachms), etc.

We come to *neoplasms*, in considering which we must not forget that we find ourselves in a period before the time of Bichat, when deep obscurity as to the tissues of the human body still prevailed. Under the word tumor they understood every unnatural elevation upon any part of the body, hence the classification of swellings approaches infinity. Plenk followed the botanists and adopted eighteen species: Inflammation, abscess, carbuncle, callus, edema, thrombus, cyst, excrescence, exostosis, joint swellings, earthy swellings, emphysema, salivary swellings, gall swellings, urinary tumors, swelling of the breast, organic tumors and false hernia. Each species was divided into varieties, so that finally their number reached 120. Thus, for example, he counted among inflammatory swellings phlegmon, erysipelas and angina; among callous tumors scirrhous, carcinoma and scrofula. Richter's classification was simpler, which we will chiefly follow on this subject. He arrayed on one side inflammatory diseases, wounds and ulcers, "the ordinary uninflamed tumor," as his chief division, and to these he added callus and carcinoma, atheroma, exostosis, aneurysm, varices, polyp, warts, corns, edema and emphysema.

The former definition of *scirrhus* as a hard, painless swelling in a glandular part, caused by blood stoppage with a simultaneous tendency to gangrene, Richter set aside and would understand under that term nothing else than a callus which arose on some part, from any cause. Unlike Heister, he did not consider scirrhus as a result of inflammation. The causes were external (contusions), or internal (syphilis, scrofula, gout, passions, etc.). Schmucker complained of the stiff fitting corsets, a legacy of the Marchioness of Pompadour. He read the ladies and "effeminate-men" a severe sermon on their tasteless and uncomfortable fashions in clothes, which were considered beautiful only because they were new. Richter also delivered a little philippic against stays as the most objectionable piece of apparel, but "many a matron who has laced during a lifetime can overcome the entire demonstration of the evil consequences of it. A too strict dietetist is like the rigid moralist who gives rules which he himself never keeps, and which are daily transgressed without harm, and hence he is derided." Scirrhus either remains benign for a lifetime, or it becomes painful, breaks, and changes into an open malignant carcinoma. As opposed to this opinion, Acrel maintained that a benign scirrhus could never become malignant, a malignant one could never have been benign. They sought to scatter the scirrhus or to cut it out. For the former purpose they used hemlock, mercury, belladonna, gummi ammoniacum, digitalis, warmth (rabbit skin), and electricity (already attempted by de Haën for tumors). J. Hunter extolled compression for solid tumors and observed that the farther development of neoplasms was arrested by this means, and sometimes they were entirely exhausted. Desault also dissipated "scirrhosities" of the anus by compression with probes. But since resolution seldom succeeds, one should not be long delayed by these means, especially if there is an immediate danger that the scirrhus may soon become malignant. If it is at all possible an operation should be performed at once, since with the failure of the resolvent remedies every delay is dangerous. As a contra-indication of the operation, Richter allowed those cases in which the scirrhus could not be clearly extirpated, and those in which tumors were present on other parts of the body where an operation could not be made; for all which were left changed invariably into carcinoma. The possibility of a relapse was admitted.

The scirrhus might also turn into a carcinoma. This view was characteristic of that time and had as a result that they regarded scirrhus and cancer as diseases of the same kind. The transformation announces itself by pricking, burning and itching, which by degrees becomes more severe and continuous. The tumor grows and becomes hard, the skin red and blue and the blood vessels in the vicinity swollen. At this stage an occult cancer is spoken of. Left to itself the tumor breaks and an open cancer ensues. The sore is very painful, has a corroded surface covered with fungous or hard excresences and hard edges; it bleeds readily and profusely and exudes an acrid, ill-smelling fluid. But not many cases begin with these symptoms; there is no pathognomonic characteristic by which carcinoma is distinguished from other abscesses, and neither Richter nor Schmucker would trust himself to answer with certainty the question as to how one might recognize a cancer. Hence it happened that many surgeons practiced many abuses in diagnosis; if an ulcer appeared bad, if it would not heal, if the cause was not known, it was called carcinoma. The search for new remedies forced the study of the pathology of the carcinoma entirely into the background. The efforts to spread new light by means of experiments on animals were only isolated. Peyrilhe, who won the prize of 1,200 livres offered by Pouteau of Lyons for an essay on carcinoma poison (1773), came to the conclusion that there is no especial carcinoma poison, but it consists only of a putrid matter which is first formed in the body upon the appearance of the disease. He proved contagion by the fact that a small incision made on a dog became very malignant after an injection of carcinoma fluid. Le Febure found that dogs ate without the least injury bread which had been soaked in carcinoma fluid (1775). Richter also did not believe that the carcinoma proceeds from a specific poison and requires a specific remedy; the generation and course vary so extraordinarily that apparently the causes are also of widely differing kinds. But Richter and also B. Bell had the firm conviction that carcinoma is at first only a local difficulty and that the cachexia does not arise until the corrupt matter has infiltrated into the fluids. The curability of the carcinoma was firmly believed in although it was always accomplished with great difficulty. Pott said in this connection: "We are not yet so fortunate as to possess a medicine which can remove a cancerous condition of the blood; when the whole body is thus infected neither our knives nor our medicines are of any avail; they can, indeed, eliminate the local ailment, but they have no effect upon a general malady in the body. Whoever speaks otherwise speaks untruth and whoever believes anything else is in error." Carcinoma of the breast appeared to be the most malignant of all, and the prognosis in general was unfavorable if the swelling had developed from a scirrhus.

The treatment was directed above all to the causes and against the venereal, scorbutic or gouty origin. But since in the great majority of cases the cause was unknown the operation remained as the only remedy. So thought most of the surgeons: Heister, B. Bell, Camper, Le Vacher, Le Cat, Pouteau, Richter and others. To [illegible] nan [illegible] was clear [illegible] operation would succeed much oftener if it were regarded, not as the last resort but as the first; the operation must be performed as early as possible, while the affection is still local. Other remedies were seldom of any assistance to him: on the contrary, they always occasioned an irreparable waste of time. That physicians acted in a conscienceless and undutiful manner when in the hope of saving the patient by medicine he allowed the precious time to elapse within which the knife could still afford a prospect of certain help. Heister considered a cure by means of medicine as impossible and all nostrums as swindles. Richter was well aware that the operation did not always succeed and that under the most favorable auspices the outcome was often unsuccessful, while under very favorable circumstances it was occasionally of assistance. This determined him to operate in cases of doubtful prognosis and never to hesitate when an operation appeared in any measure to be indicated. If it failed then it still lengthened life. As contraindications, he noted that cases in which the disease was no longer local, but was general, where all the cancerous substance obviously could not be extirpated, where a second swelling not susceptible of operation existed, of finally where another malady had arisen which made the successful outcome of an operation impossible. To eradicate all the cancerous substance clean and carefully, was his watchword. Heister said the same thing: "If a carcinoma can not be entirely removed it should not be touched, because nothing will be accomplished by so doing, the patient will only suffer useless pain and will die sooner than he otherwise would." The skin should be spared as much as possible and an attempt should be made to heal the wound with prima intentio. Some weeks before the operation an artificial sore was created in the neighborhood of the tumor and kept open for a time (Richter and Desault; to the contrary, Pouteau) and the patient was given milk foods before and after. In order to prevent a relapse Heister recommended a good diet during the whole life, forbade acrid, salt and sour foods, and in spring and autumn recommended bleeding and the drinking of mineral water; Pouteau had patients drink ice-cold water.

The utility of the operation appeared for a time to be placed in question by the publication of Monro's unfavorable results, until James Hill restored it to its rightful position. The investigations of the two Englishmen deserve all the more attention because they sought to solve the problem by figures, one of those extraordinarily rare cases in which, in the last century, statistics were appreciated A. Monro, Sr., announced (1752) that of sixty cases operated on, after two years only four were free from a recurrence of the carcinoma at the same point and in the relapsed cases the disease had always made quicker and more violent progress than if no operation at all had been performed. He therefore raised the question whether carcinoma should, in general, be operated for and whether it did not serve better to treat it with palliatives. Twenty years later Hill demonstrated that of eighty-eight patients, for whom within thirty years he had extirpated carcinoma in various parts of the body (among them eighty-four open carcinomas), seventy-eight were thoroughly cured and only ten had suffered relapse. Respecting this enormous difference Richter made the fitting remark that he doubted whether both surgeons had always had the same disease before them. Yet Hill's figures had great weight. From this time on most surgeons approved the earliest operation. Only a few espoused Monro's side and were so discountenanced that they condemned the operation entirely and left the patients to their fate. Thus Acrel asserted that in case of a true carcinoma of the breast the operation availed nothing, and in those cases where success had been attained carcinoma had not existed. In twenty-one extirpations of open carcinoma, Van Gesscher observed not a single cure and therefore declared, as did Rowley, against a too hasty operation on the mammary nodules. The consequence of his observation was that the surgical society in Amsterdam offered a prize of fifty ducats, and later of one hundred ducats for information of a single perfectly authentic observation of a carcinoma cure (1789). The Frenchmen, Campordon and Geoffrey, discarded the operation because the cancerous poison permeated the whole mass of the blood, relapse always followed, therefore the cures were only apparent, and in case of the published cures probably no carcinoma had existed. This was the teaching of the dyscrasic theory, from which the incurability of carcinoma was proclaimed.

Among the empiric remedies most prominent were hemlock, quicksilver, belladonna, quinin, arsenic (the chief component of the specific of Guy and Frère Cosme), aconite, onopordon, the leeching of the sore by toads, and other remedies. In the 70's they began to abandon these; only quacks and dabblers deceived the public with them. The most celebrated was hemlock, prized by Störck (1761). Now, A. de Haën, B. Bell, Hill, Schmucker, Schneider, Lange and Van der Haar asserted that this remedy had never been able to cure a real carcinoma, and at best could only diminish the smell. In order to test this remedy, Schmucker had it brought from Vienna and actually established a separate hospital with thirty patients suffering with scirrhus tumors. After experiments covering five months he declared that hemlock was actually injurious. So it went with almost all remedies. Pouteau denied them all curative properties, and Richter had tried them all and had no confidence in them; Schmucker also, and C. C. von Siebold, and in fact all the good surgeons thought likewise.

(To be continued.)

SOCIETY PROCEEDINGS.

American Public Health Association.

Twenty-fifth Annual Session Held in Philadelphia, Oct. 26-29, 1897, at the Hotel Walton.

TUESDAY—MORNING SESSION.

This meeting, by all who participated, is regarded as perhaps the most important of any yet held. The papers and discussions were of the highest importance. About two hundred members were in attendance and the interest of all was maintained to the close of the session. The city authorities and the Committee of Arrangements had amply provided for the entertainment of all the guests, combining business with pleasure wherever possible.

The Association was called to order at 10 o'clock by the president, Dr. H. B. Horlbeck of Charleston, S. C. After the announcement by Dr. Benjamin Lee, the Chairman of the Committee of Arrangements of the various meetings, and plans for the entertainment of the members, the report of the Executive Committee was read by Dr. Charles O. Probst, secretary of the Ohio State Board of Health, who was made secretary *pro tempore* in the absence of Dr. Watson, who had resigned the position. Each day a number of new members were elected who had signified their desire to join, and had been approved by the Committee.

Dr. Frederick Montizambert, General Superintendent of

Quarantine of the Dominion of Canada, read the report of the Committee on Steamship and Steamboat Sanitation. In connection with the relatively shorter voyage of the steamboat, a few points present themselves which it would seem well to emphasize. Passengers' bedding, those portions which are not regularly laundried, blankets, mattresses and pillows, should be freely exposed to the air, and, if possible, to the sunshine, after each trip. The somewhat common usage on inland steamboats of having the dining room on a deck below the water line is not to be commended. This position renders cleanliness and ventilation much more difficult, and certainly tends to unwholesomeness. The holds of the steamboats are more likely than those of steamships to become the recipients of the storage of perishable articles of food and freight. They therefore need to be frequently emptied, cleansed and freely whitewashed. The Committee can not allow the opportunity to pass without again referring to the all-important matter of the exposure of the traveling public on steamboats, as well as elsewhere, to the danger of contracting disease from fellow passengers suffering from consumption, who in their expectorations scatter broadcast the infectious material. Objectionable and indefensible as it is at all times, with steamboat saloons closed and artificially heated, the expectorator's filthy habit becomes especially dangerous to other passengers. The sputa drying on the deck rises as dust to be inhaled, and to add to the great list of the victims of this fell destroyer of mankind. All spittoons that it may be necessary to provide should contain water or a disinfecting solution, which should be frequently changed. It would be well that all States, provinces and citizens should add to their sanitary codes a prohibition against spitting on the floors and decks of ferry and other steamboats, and should require all steamboat companies to prominently post in their boats printed notices forbidding this spitting, and to enforce the same. This is doubtless a matter rather difficult to enforce, but any measure of success would be a definite and positive improvement upon the existing conditions. With the advancing knowledge on the part of the general public and belief in the contagion of consumption and the methods to be employed to limit and prevent its spread, to which education such printed notices may be made to contribute, an ever increasing degree of success may be confidently hoped for.

The next paper read was by Dr. EDUARDO LICEAGA, President of the Supreme Board of Health of Mexico, and Dr. JOSE RAMIREZ, of that Board.

A CONTRIBUTION TO THE STUDY OF YELLOW FEVER FROM A MEDICO-GEOGRAPHIC POINT OF VIEW.

In the port of Vera Cruz, which can be considered one of the sources in which this disease obtains a spontaneous origin, only three cases have appeared during the period of study and these all came in the month of June. With respect to other points on the Gulf coast and especially the ports we can safely assert that not a single case has occurred during this period. Passing to the Pacific coast and bearing in mind the terrible epidemic that in the year 1884 desolated that coast, we find that the Supreme Board of Health of Mexico has taken special care to prevent the disease from being imported from the Central American countries where, unfortunately, it now prevails as an epidemic. As far as regards ourselves, we have thoroughly proved that no source of yellow fever exists on the Pacific coast of the Mexican Republic; therefore, on receiving notice that fatal cases had appeared that were supposed to be this dread disease, the Board hastened to send to the port of Manzanillo one of its delegates who, through his own scientific knowledge as well as through his long residence in the port of Vera Cruz, has obtained a perfect acquaintance with the symptoms of yellow fever. Dr. Narciso del Rio, the person named, reached the port and made a careful study of the last cases that presented themselves. This investigation showed him that what was suspected to be yellow fever was nothing of the kind. It was probably a paludic fever of hemorrhagic form which, through the exceptional conditions brought about by the putrefaction of a large quantity of dead fish around the town, had assumed somewhat the form of a typhus. After the first days of October no new cases occurred. Other slight epidemics were mentioned. Once more it is necessary to show the difficulties which are encountered in establishing an exact diagnosis between yellow fever and certain forms of paludic infection that in hot countries assume an extremely similar aspect, and the serious character generally borne by that disease, so much so that those persons not accustomed to observe the two affections are often uncertain as to the diagnosis. These doubts will in the future be dissipated if, as we all hope, the discoveries of Dr. J. Sanarelli are confirmed. Dr. Sanarelli appears to have discovered the microbe of the fever, in the city of Montevido. A knowledge of the cause of the disease will not only allow us to establish the diagnosis, but also no doubt facilitate our means for attacking it in a certain manner. The present epidemic now prevalent in some parts of the coast of the United States will give physicians in these localities an opportunity to study under exceptional circumstances the efficacy of isolation and disinfection. The same epidemic has now presented a phenomenon that is unique up to this date, that the port of Vera Cruz, which three months had not suffered from the disease should now be taking serious precautions to avoid contagion from the United States, as at this moment happens when the steamer *Uto* is anchored in that port, having arrived from Mobile with three patients who have been ordered to be isolated and under observation in the Lazaretto of Sacrificio.

Dr. William Bailey of Louisville, Ky., alluded to the case of a man who came to his city from Ocean Springs where the present epidemic appears to have originated. He displayed marked symptoms of yellow fever, and subsequently died in a sanitarium after having shown every symptom of this disease. Notice was sent to the authorities of New Orleans and the latter were advised to investigate the disease at Ocean Springs. Yet in the face of the positive diagnosis of this case, it was decided that the disease at the Springs was not yellow fever. A week later, new cases developed at the Springs, and the epidemic was recognized.

Dr. S. H. Durgin of Boston, alluded to the vast importance of bacteriologic work in making the diagnosis of the disease.

Dr. Roque Maconzet of the City of Mexico, agreed on this point, and especially as to the great difficulty in making the diagnosis of yellow fever.

Dr. P. H. BAILHACHE of the U. S. Marine-Hospital Service said that Dr. Durgin struck the key-note in his remarks. A determined effort to investigate the disease to a finish and an abundant appropriation by Congress to carry on the investigation was the thing needed. Referring to Dr. Bailey's statement regarding a case of yellow fever in Louisville in August last, Dr. Bailhache wished to confirm this statement, as the same facts were known to the Bureau. In regard to the remarks of Dr. Liceaga criticising the report of tne U. S. Consul in Mexico, who stated that there were two cases of yellow fever in Vera Cruz, Dr. Liceaga denying the statement, Dr. Bailhache observed it was an unusual thing to charge consuls with giving too much news regarding the health of their stations, as, on the contrary, they were usually charged with not giving enough. He added that their information was based on the reports furnished them by the medical or sanitary authorities, and not on their own knowledge.

Dr. RAYMOND said that Sanarelli's claims to have discovered the bacillus of yellow fever had not as yet been substantiated, and it was probable that it was the same discovery made by Surgeon General Sternberg.

The discussion was now closed and Dr. A. L. Gihon, U. S. Navy, retired, rose to a question of privilege. In the report of the U. S. Marine-Hospital Service he had found that Dr. Bailhache, when reporting the action of the Committee on National Legislation of the meeting of this Association at Buffalo last year said: "The report of the Committee being of special importance to the Service, I deem it proper to state that said Committee presented to the Association the following resolution, which was referred under the rules to the Executive Committee:

"*Resolved.* That it is the sense of this Association that the Committee on National Legislation be continued and that efforts be made to influence the United States Congress to establish a Department of Public Health at Washington, D. C., and to this end it is recommended that the powers of the Marine-Hospital Service be enlarged and so organized as to provide for an advisory council composed of representatives from the State Boards of Health.

"The Executive Committee returned the resolution to the Association in the following emasculated condition:

"*Resolved,* That it is the sense of this Association that the Committee on National Legislation be continued and that efforts be continued to influence the Congress of the United States to establish a Department of Public Health at Washington, D. C.

"Upon inquiry I learned that a retired officer of the Navy took it upon himself to overslaugh the work of the Committee on National Legislation, whose unanimous recommendation would seem to entitle it to more respect, and upon his individual demand the resolution was shorn of its only practical solution."

After reading the above Dr. Gihon emphatically declared that he was the retired officer alluded to, and called upon Dr. Bailhache to explain what he meant by such a statement.

Dr. **Bailhache** asked Dr. Gihon if he had not struck it out?

Dr. **Gihon** replied that he did not, but that the Committee of twenty-five did so, of which he was only one, and asked if Dr. Bailhache thought the Committee of twenty-four other men were led by the nose by him? Upon being asked if he had not spoken in favor of this striking out, Dr. Gihon said he had.

The question of order being now asked as to two persons thus holding a talk on the floor, the President decided it was unparliamentary, and after both were seated, Dr. Gihon was given the privilege of continuing. In reply, he remarked "that any of the Executive Committee might sustain him in what he said—I am one of those who believe that the Marine-Hospital Service should not be enlarged so as to become a National Board of Health." Here the matter closed, Dr. Bailhache declining to reply.

The report of the Committee on Sanitation, with a special reference to drainage, plumbing and ventilation of public and private buildings, by Dr. J. W. **Hughes** of Montreal, was read by Dr. **Leal**. An exhaustive treatment of any of these subjects would require a volume; therefore he confined himself to the one subject of the ventilation of the plumbing system that serves for the conveyance of the house wastes, the sewage, and that are to be finally disposed of, as far as any building is concerned, when they reach the sewer. He gave technical description of plumbing matters, then continued: It is no more possible to lay down a rule covering every possible contingency called for in scientific plumbing and ventilating than to apply fixed rules to the practice of medicine. If it were, there would be little need of skilled and experienced physicians. The principles of scientific medicine and plumbing are fixed, but the application of these principles calls for the intelligence acquired by education and developed by practice. Much injury has been done by attempting to frame plumbing by laws that will apply to every case. The conditions vary in almost every building, and to adapt the principles to the special requirements requires not only practical but scientific knowledge. If the American Public Health Association would make a study of the general principles covering this question, and embody them in a code having its endorsement, leaving the practical application of these principles to those whose duty it is to apply them, much good would result.

The subject was continued by the reading of a paper on the

DRAINAGE, PLUMBING AND VENTILATION OF PUBLIC AND PRIVATE BUILDINGS,

v Dr. **John L. Leal**, Health Officer of Paterson, N.J. The importance of the subject can not be over-estimated. One of the results of civilization is that a very large proportion of mankind passes its time within four walls. With the advances of civilization these conditions become more and more unlike the primeval condition, and hence more and more harmful. There are three points: 1, every building intended for occupancy should have some special means of ventilation; 2, these means should be commensurate with the requirements of any particular building; 3, the more simple the means the more likely to be their operation. The object of plumbing is first to withdraw from a building immediately all waste products of life, the presence of which would prove harmful to health, then to prevent harm to the inmates arising from these products after removal. Not only are we threatened by the presence of these substances, but we are also threatened by certain dangers inherent in the best systems at our disposal for ridding ourselves of them. He then described at some length the various properly constructed appliances for the carrying out of these plans.

Dr. **A. C. Abbott**, Philadelphia, objected to the interpretations of the conditions to the effect that modern teaching on ventilation as formulated from exact examinations does not justify the belief that there is present, *in improperly ventilated* houses, substances capable of inducing specific diseases, but that the evil results of bad ventilation are principally seen in the personal discomfort to which they give rise. Unless the plumbing is so defective as to allow of leakage into the house of actual infective matters, it is impossible by any scientific method to demonstrate in the air of otherwise badly plumbed houses matters that can be said to stand in causal relation to disease. Experiments on the relation between the gases from sewage have failed to demonstrate that the former stand in any relation as causal of the disease. Statistics show that the health of workers in sewers, on drainage fields, and those employed in and about glue factories, is in general as good as that of the community at large. As to the drainage part of the report, he was fully in accord with the writer, and mentioned the conspicuous instances where improvements of a locality had resulted in improvement of the health of said locality.

Dr. **Durgin** then read the

REPORT OF THE COMMITTEE ON CAR SANITATION,

prepared by Prof. S. H. **Woodbridge** of the Institute of Technology, Boston. It would seem that something like interstate agitation and regulation are needed to any legislative advancement in this field of hygienic improvement. Hence it seems the better way that the movement should originate within, or at least be fostered by, some strong railroad corporation which shall set the pace for other railroads to eventually put themselves in step with. He described a new form of sleeping and parlor car.

ABSTRACT OF REPORT OF THE COMMITTEE ON CAR SANITATION

by **Granville P. Conn**, President State Board of Health, New Hampshire. The committee reported that during the past year more than ordinary interest had been exhibited in this work. That this subject has been discussed by the press, by workmen connected with railways and car construction, and that one State had, through their legislature, instructed their Board of Railway Commissioners to investigate and report upon the availability of various systems of ventilation. The report signified that the aim of the Committee was to give a *résumé* of what had taken place since the last meeting of the Association, in order that the Association may keep in touch with all who are interested in this subject.

The Committee took up first the work of the Railroad Commisioners in Massachusetts, who were ordered to report on systems of ventilation now in use, and who held public hearings at the office of their board in November and December, 1896. Several quotations were made from the report of this Committee, and it was shown that the interest manifested was not such as to cause enthusiasm on the part of the friends of sanitation as the report says: "With the exception of the railroad officials and the patentees of ventilating devices, only three persons made any remarks at the hearings, and no one of these urged the expediency of legislative action."

It was shown that three patented systems for the ventilation of cars were presented at the hearings and represented by the inventors, that "each of these inventors claimed, and apparently with entire sincerity as well as absolute conviction, that his is the 'only perfect system of car ventilation,' and that all other methods are comparatively worthless."

The questions considered by the board were arranged in the following manner:

1. "Are the methods of ventilating passenger cars now in general use reasonably satisfactory?"
2. "If not, are there any methods which have been shown by experience or otherwise proved to be on the whole more satisfactory?"
3. "Is it at present desirable that there should be any specific legislation on the subject?"

It was evident that the Railway Commission took up these questions deliberately and patiently heard all there was to be said regarding their availability, also gave due attention to what was said by railway managers as to the practicability of these devices. The report shows that the Railway Commission were not impressed with the idea that the public were inconvenienced to any great extent, as they say: "The evil does not appear, however, to be by any means so serious as it is sometimes depicted by theorists, valetudinarians, and the inventors of ventilating apparatus; and the present methods, if properly used, would undoubtedly give much better results than they do. The trouble frequently appears to be that the means provided are not intelligently and systematically used by trainmen, or that their use is not permitted by passengers."

The Committee proposed a remedy which was incorporated into their report as follows: "Great improvement could, however, be made in the condition of the air in our crowded passenger cars if the trainmen were compelled to pay proper attention to the ventilators. A regular set of instructions should be furnished them for their guidance and division officers should be instructed to pass through the train at every opportunity and to report cases where the ventilators have been neglected and the air is overheated and foul, to the division superintendent for discipline. The men would then soon learn to attend to this part of their duty. Sleeping car companies should have a code of rules printed and posted in the cars and their porters and conductors should be made to observe such rules."

The conclusion of the Board of Railroad Commissioners was in part as follows: "It has not been made apparent to the Board, by the testimony at the hearings or otherwise, that there is grievous complaint by the traveling public about the ventilation of passenger cars, on either railroads or street railways; or that there is any general demand for radical reform or relief through mandatory legislation. Much more frequent complaints come to our ears of the overheating or underheating of cars, than of their foul or vitiated atmosphere. It is perhaps safe to say that the complaints of bad or insufficient car ventilation are not more numerous or well grounded than those which are heard with respect to many public buildings and places of assembly for whose ventilation experts of high repute have been employed and no expense has been spared; and the problem is less difficult and complex in the latter than in the former case."

"It is evident from all that has been said, that car ventilation is still in its experimental stage, and that no artificial system or method has as yet been so fully perfected and so thoroughly approved by successful use, as to warrant the Board in recommending its general adoption under the constraint or regulation of law. The Board accordingly reports, as the result of its investigation, that no specific legislation on this subject appears to be at present expedient."[1]

After commenting on this report, the Committee in discussing the importance of thoroughly educating men in any and all duties which they are expected to perform, said: "Let us hope in the future the 'School of Instruction' on our railways will be made to include as much of the elementary principles of hygiene and sanitation as to insure not only courteous treatment from trainmen, but also the best possible application of such devices as are being used in heating, lighting and ventilating the coaches. We are ready to admit that no amount of training will furnish brains to any class of people, but to educate men thoroughly in the work they are expected to perform, will insure better results and less disappointment than with untrained employes." .

The Committee gave newspapers great credit for having done a great deal to educate public opinion in the matter of car sanitation, quoting liberally from the Boston daily press in this matter of which the following is an example: "Under the conditions we have just named—the absence of dust, smoke and cinders—traveling by railway in summer would be transformed from a dreaded ordeal into a decidedly agreeable experience. Those who have ridden in the electric cars over a greased track-bed do not need to be told that there is something positively exhilarating in thus rushing through the pure air, particularly on a hot day in summer. The experience would be precisely the same in railway trains if the railway companies would make the relatively slight reforms needed to do away with the nuisances to which we have referred. Under such circumstances the traveler at the end of a 500 miles' trip on a railway train would be just as free from the sense of dirtiness as though he had made the same distance on a sailing vessel instead of a railway train. This improvement is of vastly greater importance to the traveling public than that which consists in having bathtubs and barber shops on railway trains, and is one which, apparently, can be brought about at relatively slight expense. In other words, it is much more a question of efficiency in administration, in using the best methods, than of increasing corporate outgo."

The Committee referred to the fact many large roads have an advertising department complete in all its details, with a competent head to direct its work, and said: "If this department would keep up to date, it must take cognizance of the sanitary condition of trains, stations, yards and grounds. That as people are traveling across the continent and from State to State in the pursuit of health or pleasure, they pay well for their accommodations, and while it is pleasant for them to have the press agent of a road describe in an agreeable manner the resorts to which his road would invite them to make a home, yet, however beautiful such resorts might be when reached, and however much enjoyment might be taken, and rest obtained while sojourning in these elegant and palatial hotels, yet to be carried, to such a place in unwholsome and filthy trains, and waited upon by discourteous servants of the road, will do a great deal toward destroying any influence which the advertising agent may have created."

Reference was made to the epidemic of yellow fever in the south, and said: "It is generally admitted that yellow fever is a preventable disease, and if so, interstate and municipal authorities along the Gulf coast are responsible for its outbreak. It is true that railways, like individuals, have to take their chances of an occurrence of epidemics that will interrupt business relations, yet at the present time, with all the power that is granted by federal and State governments, someone must be negligent or inefficient, to allow a disease of this character to obtain a foot-hold and spread itself over three or four States."

The disinfection of railway coaches was taken up and in the discussion of this question, reference was made to the work of the United States Marine Hospital Corps and of papers read by Surgeon-General Wyman and Dr. Kinyoun, before an Association of Surgeons of the Southern Railway Company, in which Dr. Kinyoun explained the manner of using formaldehyde. The Committee said: "The work of disinfection with formaldehyde can not be left to inexperienced or untrained men. Whenever it is performed by using the formaldehyde gas, it becomes necessary that a trained expert has charge of the work and in mixing the solutions necessary for it to be used as a germicide requires care and experience. There is no doubt but what the chief surgeon of the road might, in a reasonable length of time, educate a good and bright foreman of the cleaning department to that extent, that his work would be fairly reliable; yet, in times of epidemics, when car service was running through an infected section of the country, it would be necessary for a thorough-going expert to take charge of this work. I have had no experience with the use of formaldehyde gas as a disinfectant, but have been cognizant of several failures to do good work by reason of the inexperience of the would-be operators. For more than two years I have used the solution of formaldehyde in surgical work, and consider it far superior to any of the germicides which have yet been brought to the notice of the surgeon. Its power to prevent suppuration, or to lessen its destructive influence where pus was present has been wonderful in its results, and very gratifying to the patients."

The report closed by referring to the work of the Master Car Painters' Association, which held its twenty-eighth annual meeting at Old Point Comfort, Va., Sept. 8 and 10, 1897. The Committee said: "Members of the American Public Health Association as well as of the Railway Surgeons' Association will remember that the writer has always advocated a union of work and an interchange of ideas between the practical mechanic and the sanitarian; and I am very glad to extend a most hearty welcome to these co-workers in sanitary science, and bid them God speed in their endeavor to effect a reform in railway sanitation; for whenever work of this kind is being pushed forward by a demand for reform on the part of the public and has the approval of the constructive mechanic, the power is one of irresistible force, and grand results must naturally follow."

The report gave liberal quotations from the papers and discussions of this convention of mechanics, giving the rules and regulations for cleaning passenger cars at terminals adopted by the Cleveland, Cincinnati, Chicago and St. Louis Railroad. There were thirteen of these rules and regulations, which are too long for a mere abstract of the report. In discussing these rules and regulations the Committee said: "They may be the best and most effective that are possible to be enforced by men who are uneducated in the scientific principles of sanitation; and, of course, they can be amended whenever the advanced education of the train and shop men demand a more effective hygienic service.

"Thus far, nothing strictly of an automatic character has been devised to regulate the heating and ventilating of cars and produce first-class results. As yet these seem to be unsolved problems, and any one who has occasion to investigate these questions is ready to admit that they present some perplexing points that are of great interest, yet are entirely outside the domain of questions pertaining to the hygiene and ventilation of ordinary dwellings and dormitories. The fact that a car is a house on wheels, sometimes standing still and at other times moving at a rate of from ten to seventy five or even more miles an hour, presents obstacles to be overcome in the matter of lighting and ventilation that never have been solved by architects or others having to do with the introduction of heat, light and ventilation in ordinary dwellings. The ventilating and heating of cars running into the north and east must go hand in hand for at least eight months in the year. The sanitarian can easily point out some of the defects, and possibly suggest some ideas that will be of assistance to the practical mechanic in overcoming difficulties in the ventilating and heating of a railway train; but I suppose it will be a long time before any of us will make our fortunes in solving these problems alone, and thereby be deserving of the gratitude of the traveling public.

"However, the great work is slowly going on, and we can well afford to abide our time. As an Association we may without egotism congratulate ourselves that we have been the means of introducing by our educational work the beginning of a great reform in car sanitation, and having enlisted the public, the press, the mechanic and a legislature, we may feel that the work is well begun, and will continue to go on steadily attracting increased force in its onward career."

(*To be continued.*)

PRACTICAL NOTES.

Acute Intestinal Obstruction.—McArdle (*Dublin Journal of Medical Science*, Oct. 1, 1897) in concluding a paper on this subject offers the following suggestions in case of difficulty in finding the site of obstruction: 1. Follow the engorged coil of intestines upward and downward until the point of obstruction is reached, or turn out all the intestines. 2. Remove all fluid from Douglas' pouch and the loins, by irrigation with sterile water. 3. Restore the color of the bowel, and establish peristaltic movements by heating with neutral saline solution. The removal of the primary cause of intestinal obstruction is not always followed by relief of the symptoms. 4. Should there be difficulty in returning the intestines, elevate the pelvis in the Trendelenburg position, or if necessary, open and wash out. 5. Before all, and above all these conclusions, the following rule should be observed: "When a surgeon is called to a case of complete obstruction of the bowel, with evidence of peritoneal effusion, it is his duty to operate at once."

Diagnostic Importance of the Amount of Chlorids in the Urine.—In chronic affections it seems to be definitely established that progressive or abrupt diminution of the chlorids in the urine indicates a serious phase of the disease, when it is not due to special alimentation. Fieux contributes to the *Arch. Clin. de Bordeaux*, September, a study of the chlorids in the urine of pregnant women, concluding with the statement that the passage of chlorids into the urine is in direct proportion to the permeability of the renal filter for toxic products, and hence, in normal pregnancy or with slight albuminuria the amount of chlorids is always large, averaging 15 grams and never less than 12 grams in twenty-four hours. But if the albuminuria is complicated with vomiting, vertigo, etc., the amount of chlorids is materially diminished, and evidently in parallel proportion to the degree of intoxication. Antouchevitch having observed that the vomiting of pregnancy resembled the symptoms of ani- deprived of salt administered salines in large quantities obtained a prompt, complete and permanent cure. He rted at Moscow that his usual combination is Botkine's mixture, phosphate of lime, Glauber salts and bromids.

Removal of a Retro-bulbar Tumor with Preservation of the Eye.—Weiss (*Wiener Medizinische Wochenschr.*, 1897, No. 42, p. 1958) reports the case of a child, a year old, whose parents had noticed increased size of one eye shortly after birth. The eye was pushed not only forward but also toward the median line. Operation was undertaken, a curved incision being made through the skin above the outer portion of the orbital margin, which was resected and turned outward. A bluish, translucent cyst came into view. In the endeavor to free the wall of the cyst this ruptured and it was seen that it continued far into the orbit in the form of a tube. In consequence of the free hemorrhage the operation was interrupted, to be resumed two days later. The remainder of the cyst, which extended into the optic foramen, was dissected free and divided, leaving some doubt as to whether the whole of the growth had been removed. The wall of the orbit was now replaced and the wound closed. Recovery took place without complication. The exophthalmus disappeared. Ophthalmoscopic examination disclosed a pale papilla.

The Treatment of Hydrocele by the insertion of sterilized catgut within the tunica vaginalis. Van Schaick (*Medical Record*, Oct. 30, 1897, p. 624) reports a group of ten cases of hydrocele treated successfully by the following method: After thorough disinfection the scrotum is tapped with a small trocar in order to secure a rather slow evacuation of the fluid. A catgut ligature of medium size is introduced within the cannula as soon as the serum begins to flow and is rapidly pushed within the tunica through the cannula until about eight inches is passed through it. When all of the liquid is evacuated the cannula is removed and the catgut hanging out of the puncture is snipped off with the scissors as close as possible to the scrotum. By manipulation of the scrotum complete entrance of the catgut within the tunica is secured. The wound is then sealed with collodion. If the asepsis has been perfect there is no possibility of the occurrence of any infection. The rather nauseating pain that sometimes occurs after iodin injections is commonly absent. No febrile action takes place.

Benzosol in Phthisis.—This drug was used in a number of cases of tubercular disease in the Cincinnati Hospital, during the summer and fall of 1896, in the service of Drs. Geo. Fackler and E. W. Mitchell. The gastro-intestinal symptoms were markedly changed for the better; and in this way by limiting vomiting, by lessening the number of stools, the changing the character of the stool from watery to a rather firm consistency, the lives of a number of patients were prolonged; not only this rather doubtful benefit, but the relief afforded by checking the diarrhea, made them more hopeful of the future and banished their mental depression. In the two cases in which a fatal termination supervened, the abolition of diarrhea was the most striking result of the treatment; the stools diminished from six or eight per diem, to one or two. It is but fair to say that these fatal cases had well-marked signs of cavity formation when the treatment was instituted. Two cases of the incipient form of phthisis, who were reported "discharged well," had entered the hospital complaining of diarrhea, and made no mention of any pulmonary trouble. The experience, then, would only go to confirm what is being reported by others, that benzosol is an intestinal antiseptic, and that the good results obtained in phthisis are due mostly to its beneficent action on the gastro-intestinal tract. Benzosol is a benzoate of guaiacol, and it is probably due to the presence of the latter, that such good results were expected of it in the treatment of tuberculosis. It is best given in from five to ten grain doses, three times a day, a quarter of an hour after meals.—*American Therapist.*

A Simple Method to Obtain Separately the Urine from Both Kidneys.—To obviate the dangers attending catheterization of the ureters and other procedures for determining the character of the secretion from each kidney, Neumann (*Deutsche Med. Woch.*, 1897, No. 43, p. 690) has devised an instrument by which the bladder, especially in women, is devided into equal portions, and the urine discharged into each finds its way out of the ureter through separate channels. This appliance consists in a tube of thin metal 4 cm. long, 1 cm. thick, carrying within its lumen a solid septum extending 4 cm. beyond the proximal extremity and thus forming a partition within the bladder and the ureter 8 cm. long. The divisions formed in the bladder terminate at the distal extremity of the tube in two smaller tubes, to which test-tubes can be attached and the secretion from each kidney collected separately. The free proximal extremity of the septum terminates in a blunt point, from which pass off to either side two fine curved wires. The tube and its prolongation are curved after the fashion of Hegar's cervix-dilators, so that the instrument adapts itself readily to the posterior aspect of the symphysis pubis. In the employment of the device the patient sits at the edge of the bed, with the feet supported and the thighs spread far apart. The conical proximal extremity of the instrument is introduced into the ureter with its convex aspect forward. The urine present in the bladder escapes. The viscus is then irrigated with warm boric acid solution and all fluid is removed with the aid of a finger introduced into the vagina. The urine, as it is discharged from either ureter, now collects in the bladder on either side of the artificial septum and is eventually discharged through the small tubes.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, 100 Washington St., Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the *Editor*, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street (Occidental Buildings), Chicago.

Original communications are only received with the understanding that they are exclusively contributed to this JOURNAL.

SATURDAY, NOVEMBER 13, 1897.

THE LATE LEPROSY CONGRESS.

The recent International Conference on Leprosy at Berlin does not, so far as reports have been obtained, appear to have developed anything specially sensational, either in its discussions or its findings or resolutions, as perhaps might have been expected to be the case. The conclusions as to the hopelessness of treatment, the recognition of Hansen's bacillus as the cause of the disorder and its non-hereditary character are not startling in any sense; the temperately expressed opinions as to the spread of the disease and the necessity of isolation that seem to have been offered are also in the same line of moderation, and the further rejection of the proposition to establish a permanent international commission on leprosy may also probably be accepted as another indication of the same non-alarmist tendency. There was evidently a considerable degree of individual difference of opinion on certain points, but the general tone of the convention, judging from its utterances as given in the press, was opposed to the excitement of any general alarm on the part of the public as to the possible dangers from this disease, at least as far as the principal civilized countries are concerned. One thing, however, was brought out clearly, viz., that the leprosy-producing organism is extremely abundant in the disease, according to some accounts even pervading the atmosphere around the infected individuals, and yet that there seems to be, in temperate climates at least, an almost universal insusceptibility to the contagion. We say "almost universal," for the conclusions that the disease is not hereditary and the occurrence of leprous foci in Norway, Nova Scotia and elsewhere in temperate climates, must necessarily imply the existence of susceptibility to contagion outside of tropical regions. Just what constitutes this susceptibility does not appear to have been settled by the Congress, but it appears to have been considered as exceptional, and possibly as due to some special conditions of health in the individuals exposed. Against this common immunity we have the fact of the almost infinite opportunities of contagion in the abundance and the diffusion of the bacilli from any source of infection, and taking both facts into account, it would seem reasonable to use precautions against the disease. Even if absolute isolation be unnecessary in this climate, the free association of lepers with the public and their mixing with crowds in cities and in public assemblages is decidedly undesirable. The fact that by isolation the number of lepers in Norway has been reduced very decidedly is evidence of this, and the decision of the Congress that isolation is desirable, and that the Norwegian system is to be recommended, is only what ought to have been expected, and can not be deemed in any way an extreme expression of opinion. The view held and expressed by some dermatologists that leprosy is non-contagious in this climate, and that there is no danger or impropriety in its victims going freely about and being treated with other diseases in hospitals, is hardly supported by the facts here developed. There may be some difference in the degree of contagiousness of the anesthetic and the tubercular forms, but in the latter especially it would seem that precautions against contagion are desirable. The long and variable period of latency of the infection is another point of importance; one can not say with certainty whether he is or is not infected, and it may be within the possibilities that an infection obtained in temperate regions where it remained entirely latent might develop into the complete disease on a later residence in the tropics.

Another fact that seems to have been discussed and admitted in the Congress was the possibility of forms of leprosy existing among us unrecognized; many of the cases of syringomyelia that are reported are, for example, to be looked upon as suspicious, and the same is true of Morvan's disease, in which in Brittany the presence of Hansen's bacillus has been determined by one or more observers. The bacteriologic identification of syringomyelia with leprosy is not so definite, but we have at least one reported observation, that of PESTANA and BETTANCOURT, of the finding in it of the lepra bacillus. It is not impossible that there are other as yet unrecognized modified forms of the leprous infection existing among us.

The assertion positively made that the germ of leprosy is found only in the human species is a satisfactory one, since could it be conveyed by the lower animals, the chances of mischief would be multiplied.

We can satisfy our egoistic and philozoic tendencies together with such facts as this.

It is evident that there are yet many important questions relative to leprosy that are left unsettled by the Congress, among them those of the vitality of the Hansen bacillus, the exact modes of contagion, the reasons for immunity, the exact climatic and dietetic conditions favoring it, etc. The Congress probably acted judiciously in not endorsing any alarmist opinions, while yet advising reasonable precautions against possible contagion and spread of this loathsome disorder.

APLASIA OF THE GALL BLADDER AND THE BILIARY DUCTS.

In 1892 JOHN THOMSON[1] collected all the cases of congenital absence of the gall bladder and the biliary ducts described in the literature, namely, forty-nine, and added a case of his own, making the total number fifty. Recently KR. THUE of Christiania describes a new instance.[2] It concerns a newborn girl, twin birth, the other child being well and living at time of this report. Icterus, present at birth, increased rapidly; the liver enlarged and emaciation progressed, death occurring in two weeks. The postmortem showed an enlarged granular liver of olive-green color, with bands of fibrous tissue ensnaring islands of hepatic tissue. Any gall bladder, biliary ducts or sign of any biliary papilla could not be found. In addition there was a healing pericarditis with a fibrinous exudate. The microscopic examination showed broad bands of fibrous tissue surrounding groups of and also single acini, as well as penetrating into some lobules separating the cells from each other. In the connective tissue were clumps of yellowish-brown pigment and collections of round cells. All the liver cells were yellowish. In the connective tissue were also small ducts lined with a cubical or flattened epithelium, the lumen being filled with yellow clumps. Sections through the fibrous tissue occupying the site of the gall bladder showed no sign of the gall bladder or any part of it. Bacteria were not demonstrable in the organizing pericardial exudate.

The clinical picture of absence of the bile ducts and the gall bladder corresponds to that of retention icterus in general. In the beginning the condition is very apt to be mistaken for an attack of icterus neonatorum. The deep icterus may require from eight to ten days for complete development, because the liver cells do not perform active secretion until some days after birth. Hence the steadily increasing aggravation of the symptoms in case of absence of the biliary passages will be the principal factor in the differential diagnosis of this condition from icterus neonatorum. The average duration of life of the children without biliary passages is about four months; some have lived for eight months, others die a few days after birth.

According to MINOT,[3] the liver is formed from a diverticulum from the intestine, which very soon divides into two. These evaginations consist first of solid columns of cells that afterward separate so that a lumen is produced. The gall bladder is formed from an outgrowth of the right primary diverticulum. Absence of the gall bladder and of the biliary passages may arise from an arrest of development of the originally solid canals or because connective tissue proliferation of inflammatory or other origin gives rise to obliteration of the canals sooner or later after they are formed. LORRER[4] regards syphilis as the most likely cause of these anomalies, perihepatic processes in the porta hepatis leading to obliteration of the passages. JOHN THOMSON[5] regards syphilis as an exceptional cause, inasmuch as in twenty-nine of the fifty cases collected by him nothing is stated pointing to syphilitic infection of the parents. In THUE'S case there were no indications of syphilis.

In the majority of cases described there is a history of evacuations of meconium. Now, the greenish black color of meconium is due to biliary coloring matter and hence it becomes necessary to assume with THOMSON that in these cases the biliary passages have been imperfectly formed and the resulting partial retention of bile gives rise to inflammatory changes that end in a complete obliteration without much, if any, traces to indicate the exact genesis of the anomaly.

The secondary changes in the liver in these cases are of considerable interest. These changes are essentially those of a biliary cirrhosis. The points of difference between this form of cirrhosis and the so-called hypotrophic cirrhosis of the French, which must be regarded as a disease *sui generis* due in all probability to some obscure form of infection, need not be discussed in minuteness at this time. By biliary cirrhosis in the strict sense ought to be designated the forms of interstitial proliferation that depend directly on occlusion or obstruction to the outflow of bile. JANOWSKI[6] made a study of biliary cirrhosis and came to the unequivocal conclusion that it is due to obstruction of the bile and that it can be produced experimentally by the ligation of the ductus choledochus. Now, in congenital absence of the biliary passages, nature has, so to speak, made this experiment. As a rule the clinical history in these cases points to a progressive enlargement of the liver. This enlargement is due to the steady increase in the amount of the connective tissue. On account of the increase in the biliary pressure bile capillaries may burst, the bile is infiltrated among the liver cells and its pressure on the blood capillaries produces anemia of the liver cells, which in conjunction with the direct action of the bile, leads to necrosis of the hepatic cells, followed by an overgrowth of connective tissue. The necrotic areas act as foreign bodies and induce round cell infiltration and connective tissue proliferation. These changes occur more or less irregularly—at times it surrounds many acini, at other times small remnants of acini are found in the connective tissue, generally it manifests a marked tendency to invade acini from the periphery.

HYSTERIC ACCUSATIONS AND HYPNOTISM.

Hysteric accusations are of perennial interest to physicians, albeit the lawyers occasionally suffer as much from these, and the clergymen even more. Cases of hysteric scandals are exceedingly frequent under the fostering care of the sensation-monger press, and are of late conjoined with crude popular notions of hypnotism, as they were during the hypnotic epidemic of half a century ago in the United States.

Dr. BRIGHAM, of Utica, reported the following case (*American Journal of Insanity*, April 1848): A man was accused, by an hysteric lunatic, of an attempt to murder her. The delusional origin of the accusation was proven by Dr. BRIGHAM, who also recognized the hysteric phase. The patient was hypnotized by a layman "mesmerizer," who did not believe the accusation. Her narration of the story during the hypnotic state varied decidedly from that given in the conscious state. The "mesmerizer," who regarded the woman as a lunatic, testified to these facts. The woman gagged herself, tied herself up, and did analogous hysteric tricks now familiar to neurologists. The accused was acquitted.

This case in certain particulars bears a decided resemblance to the GRACE DARRELL case of Jacksonville, Fla. Two years ago this girl, then at the age of 20, claimed to have been kidnapped, taken to the woods, stripped of part of her clothing and tied to a tree where she was found the next morning. Four young men were charged with the crime, arrested and convicted, but a new trial was granted. The young men were afterward tried in the United States court, charged with sending improper letters to Miss DARRELL.

The prisoners were convicted but again the court set aside the decision. Recently Miss DARRELL made a sworn confession that her testimony was false and that the letters were written by her guardian and others for the purpose of convicting the young men. When this confession become known she was taken to the newspaper offices by the guardian, and there denied ever having made it. She was brought into court and again denied having made the confession, despite the fact that it was witnessed by four prominent and trustworthy citizens. The guardian was present when these denials were made. Miss DARRELL escaping from the guardian's residence, declared the confessions were absolutely true. She says her guardian has a Svengali-like influence over her, and that she is powerless to do otherwise than he tells her to do. To the features of ordinary hysteric accusations, this case adds a by no means improbable charge of suggestion, but this suggestion is not greater and no more criminal than that made to ordinary hysterics by well-meaning but credulous sensationalists, when an hysteric accusation is once started.

Hysterics have far from infrequently indulged in letter-writing performances similar to those of the DARRELL case. This occurred in the following (*Alienist and Neurologist*, Vol. 16): A milliner complained that her store had been fired several times, and that obscene letters had been sent her. She confessed later that she set fire to the store and wrote the letters. She implicated a young man and stated she had been his mistress. He was arrested but she failed to prove her charge against him and he was released. She was then indicted for perjury. In her confession read at the trial she said that she fired her store in order to get money to go to New York and find the young man with whom she was infatuated. Drs. WILLIAM A. HULSE and FURMAN NICOLL testified that the defendant had suffered from hysteria and temporary insanity resulting from dysmenorrhea. Dr. L. C. GRAY testified that under the right and wrong knowledge test of the New York code, she was not insane. The jury acquitted her in clear defiance of the code on the ground of insanity.

LEGRAND DU SAULLE ("Les Hystériques") describes cases where women formed the delusion that they had been struck or stabbed by others after having inflicted blows and wounds upon themselves. In one instance a young woman was found by her husband lying on the floor of her room in a fainting fit, her face covered with blood. She stated that she had been attacked by armed men. The Paris newspapers related the case and within three weeks two similar events occurred in the French metropolis. All these cases proved to be fabricated by the supposed victims. A young girl wounded herself slightly with a pistol. She gave the police authorities the most minute details about an imaginary assassin who, according to her account, fired the shot, but she was found to be highly hysteric, and it was proved that she had wilfully wounded herself. In a third case (in Dr. DU SAULLE's experience) a young woman was found, in a railroad carriage, stabbed in the left side. The incident caused great excitement, but it was proved, contrary to her assertions, that she had inflicted the wounds herself and was a hysteric subject. A housemaid was found lying behind a door bound, gagged and covered with bruises. She stated that she had been brutally attacked by two burglars with blackened faces, but she was a highly hysteric woman and there was conclusive evidence that she had contrived to tie her own hands and gag and bruise herself.

TARDIEU cites the case of a woman of Courbevoie who wished to pose as a victim of political conspiracy which she pretended to have discovered. One night she was found at the door of her apartment in a state of great mental perturbation. She could not talk, but stated in writing that she had been attacked outside her own house by a man, who attempted to garrote her, at the same time striking her twice with the dagger. Only the clothing was injured, the body of her dress and her corsets being cut through but at different levels. She tried to make out that the attempt at strangulation had caused dumbness. TARDIEU remarked in her hearing that this infirmity rapidly disappeared when produced under circumstances of this kind. She soon managed to regain her speech and in a short time admitted that the whole narrative had been evolved out of her inner consciousness.

In a case reported by LEGRAND DU SAULLE, an hysteric female sent five persons to Cayenne (the French penal settlement) on a charge of rape. A member of the French Medico-Psychological Association suspected, from an after-examination of the alleged victim, that the whole story was of hysteric origin. Through his efforts the innocence of the prisoners was demonstrated and they were released.

TOULMOUCHE has reported the case of a young girl given to devotional exercises and much inclined to flagellation and asceticism. She one day cut herself six hundred times on various parts of the body, with scissors. She asserted these wounds were made by a man who tried to outrage her. She finally confessed that the injuries were self-inflicted. HUCHARD has had under observation an 18 year old girl who accused the vicar of the parish of having raped her. She stated that one day, while she was praying in the church, the vicar shut all the doors and requested her to go with him into the sacristy. There (she claims) he made obscene proposals to her and, as she indignantly refused, he pointed a dagger at her, she fainted, and during the faint he (she alleged) violated her. She was questioned during the trial. Her replies to the questions of the medical expert exciting suspicion an examination was ordered (by the court) which revealed that she was still a virgin.

TARDIEU has reported the case of an inmate of a Gascony convent who claimed to have been made the victim of all sorts of outrages therein. Her father, with full faith in what she said, denounced the alleged criminals. Finding, however, that his daughter's story was untrue, he took his life. In another case cited by TARDIEU, a girl charged two young men with having violated her and introduced into her rectum and vagina, stones, splinters and iron, which had to be extracted with great pain. She had convulsive seizures, followed by paralysis. The two men were convicted and had been imprisoned for more than a year when the false nature of the accusation was discovered.

The psychologic *raison d'être* of these accusations has been carefully pointed out by DESCHAMP'S (*Bulletin général de Thérapeutique*, 1891). The The general mental characteristics of hysteria are, he remarks, an absolute want of equilibrium in sensibilities and will power. There exists a mobility of humor in direct relation with facial impressionability to external influence (external ideas or perceptions) or to internal states (intrinsic ideas). The nerves vibrate to all sentiments, coming from within or without, which are registered without proper relations. One fact chased by another is forgotten. Another produces a momentary hyperexcitation which takes the place of truth, whence it is that falsehood is instinctive, but the patient protests her good faith if accused of the same. This lack of equilibrium leads to decided modification of the mental faculties. Intellectual activity is overexcited, but in diverse degrees and in variable ways, according to the particular tendencies adopted. Absorbed by a preoccupation or controlled by an idea, they become indifferent to all else. Their ideas are abundant and they *rapidly pass from the idea to the act. Their vivid* imagination, coupled with a bright intelligence, gives them a seductive aspect, but their judgment *is singularly limited, attenuated or false.* They judge excellently from a non-personal standpoint. They are quick at discovering faults, even of their own relatives, but faults attributed to themselves are repudiated. Their memory is capricious. They forget their faults and their acts done under impulse, albeit these may be consciously done. They frequently make charges of immoral conduct against both men and women, often with a desire of securing notoriety, often, as SPITZKA ("Manual of Insanity") remarks, with the object of indicating their own desires, and equally often from a voluptuous enjoyment of the suffering caused by the accusation. The responsibility for these is legally doubtful. They are often at first vague and indefinite, but are given form by the suggestion of others honestly desirous of punishing a supposed *wrong. In all accusations by neurotics,* this delusional factor must be taken into account legally, both for the benefit of the individual and of society.

CORRESPONDENCE.

Observations on the "Code."

NEW YORK, Oct. 31, 1897.

To the Editor:—The "Code" is noble, a law irrevocable, supreme wherever the doctor wends his way, ruling an army of learned and cultured men. Its genesis is lost in antiquity. It is noble, but not more so than the unified profession whose ethics it formulates, failing only in so far as those whom it would govern are human, and to be human is to fail as well as to succeed. The "Sermon on the Mount" has been attacked, so has the Code. It has been said that a gentleman requires no "rule of conduct;" true, but all are not gentlemen, and so there is need for the rule of ethics as there is need for the "Sermon;" neither will be too old until the time has come when every man does unto his neighbor as he would be done by. However, it is not our purpose to defend; it is not necessary.

Those who as yet are breasting the current, struggling where the rocks are jagged, where the eddies swirl, fain to reach the placid waters beyond, the status of the successful practitioner of merits proved with laurels won; these are the ones who find it most difficult to correlate conduct with the exactions of the "Code."

When one by one the rungs of the ladder of fame have been courageously reached and passed, and there is an infinity between the first and the last, then it is that the individual is best adapted to the "Code." Now, a position is occupied so lofty as to be everywhere easily observed. A chance misstep and the labor of years is all for naught; and again, one now comes to love the "Code," to realize its justice, to acknowledge the verity of the principles on which it is founded. These things hold such an one in loyal and constant obedience to the ethics of "our profession."

But in what manner do its provisions apply to those for whom the top of the ladder is yet a weary climb? They more frequently fail, and the reasons are manifold. Entering on the practice of a profession already overcrowded, finding competition keen and uncharitable in the struggle for sustenance, they see apparently well-founded cause for sometimes disregarding the mandates of a Code which, did they but know, would prove their best, most steadfast friend. In these days of newer economics and rapidly changing ideas, it is difficult to get the younger men to properly regard principles of conduct which some are pleased to term "idealistic" and "not applicable to the times." They forget that the "Code" was made for one and all, makes the weak the equal of the strong, eliminates mediocre competition, is the crystallized wisdom of the army that has gone before; that it never grows old, for, like the drama of Shakspeare, it is founded upon a truthful interpretation of human nature, in which there is little change from Galen's time till now. Even those most prone to break the rule can not but acknowledge its high place.

Our profession is everywhere banded into groups whose object and duty it is to have a proper regard for the general welfare, and to enforce the principles which we know are for the good of all. If an erring brother filches from you your purse, or what means the same, illegitimately deprives you of a patient, do not overlook the action, grow cynical, sneer at the "Code," but rather place the circumstances before the properly constituted society. Then the erring brother will be called upon to walk the "straight and narrow path," and if he chooses not to do so will be branded for what he is. Patient endurance under such circumstances makes he who endures a party to a course of action which, if prevalent, would undermine the very foundations of the profession. So take heed; for upon you who have the way before you much is depending, and let it not again be said that four young physicians of New York City successively bid for an expected *accouchement*, the fourth and successful bidder agreeing to take the case for $5.

E. S. B.

Homeopathy vs. Rational Practice.

LA PORTE, IND., Oct. 22, 1897.

To the Editor:—Yesterday I received from my publishers, the W. T. Keener Company, the JOURNAL for September 25, on pp. 661–2 of which is notice of my little book "Principles of Medicine." Will you permit me to correct the erroneous impression which the closing words of that notice are likely to have made upon your readers? The writer quotes me as follows: "'It is perfectly well known that a very large majority of us homeopathists do not repudiate practices which we think useful, although they are not instances of homeopathy.'" The quotation is (substantially) correct, but his interpretation of it is misleading when he continues: "In other words, according to our author, whatever he is satisfied cures the patient is homeopathy." Look again at his quotation from me: We "do not repudiate practices which we think useful, *although they are not instances of homeopathy.*" Does that bear the interpretation that he has put upon it?

I have great confidence in the utility of so defining the cure sought in any given practice of homeopathy as to distinguish that cure from any sought in rational practice, and in the utility of discussing homeopathy as a matter *of opinion.*

Very sincerely, CHAS. L. MACK, M.D.

A Misrepresentation.

CHICAGO, Nov. 8, 1897.

To the Editor:—In *Leaves of Healing*, dated Oct. 30, 1897, edited by Mr. J. A. Dowie, copies of which have been liberally distributed to Chicago physicians and others, appears the following in the guise of an alleged quotation from a paper read by myself to the Sunset Club:

"The doctors of Chicago are divisible into three classes, the first are liars, the second are damned liars, and the third are experts and they are the biggest liars of all."

At the meeting of the Sunset Club March 1, 1894, I read a paper on "Expert Testimony," in which occurs the following passage (official report, p. 3): "But closer familiarity with the practical workings of the system reveals a still more serious flaw, one which has given rise to the time-honored epigram that witnesses may be divided into three classes: liars, damned liars and experts. Instances of deliberate lying by expert witnesses are not unknown; our real estate friends furnish especially brilliant examples."

A comparison of these two quotations renders comment unnecessary. WILLIAM T. BELFIELD, M.D.

Edema Universalis(?)—Varia.

DETROIT, MICH., Nov. 5, 1897.

To the Editor:—A year or so ago I was called to see a baby three months old having pronounced edema of the extremities, anasarca of the scrotum and a general puffiness of the eyelids, face, etc. The urine on chemic and microscopic examination showed no abnormality to account for the affection. Heart and lungs normal.

Recently Dr. Steinbrecher of this city, in his regular family practice, saw a somewhat similar case, save that there was no anasarca of the scrotum. Heart and kidneys were normal in this case also.

In the literature at my command, containing the most recent and voluminous reference works, I fail to find a description of a similar condition and would therefore ask you whether or not I am justified in calling it edema universalis?

I approve of your continued efforts to establish a department of health. Such an organization would put the medical profession at once on a higher scale, at least so far as the respect from the people is concerned. It would also lead to a uniformity of health laws for each State and Territory of the United States and pr[illegible] or[illegible] the [illegible] physicians, so that one examination should entitle an M.D. to practice throughout the union.

I could in addition to this say a good many flattering things for the JOURNAL, having seen it improve and progress since my arrival in this country, but shall not do so at present save that I wish to sustain you in your position in regard to the newer orthography.

When in Germany some time ago a new orthography was submitted to the Secretary of Education, the number of opponents was immense. But today, in spite of them, German is written more rationally—such words as *todt* being spelled *tot; roth, rot; muth, mut;* etc.

In this connection I wish to say that in my humble opinion we affix our title M. D. to the wrong side of our names. The old Austrian style of putting the abbreviations "Med. Dr." before our names seems to me the correct one, and unless you object to it would like to see my signature put that way.

Respectfully, MED. DR. GUSTAVUS M. BLECH.

The Cure for Dipsomania?

MIDLAND, TEX., Nov. 4, 1897.

To the Editor:—Will you be kind enough to inform me how I can procure the formula for the so called "tonic" that is used by parties in giving the "whisky treatment?" Can you refer me to any issue of the JOURNAL or other medical publication containing it? W. K. CURTIS, M.D.

PUBLIC HEALTH.

A Preliminary Course of Training for Ship Doctors is being organized at Hamburg which will be required of applicants in future. Italy requires proof of a certain knowledge of hygiene and two years' practice, and in France applicants have to pass a special examination in epidemiology and sanitation.

A Possible Explanation.—Beri-beri is said to be particularly prevalent in the Dutch Indies. Dr. Eykmann made an important discovery in the prison of Sourbaya. While on July 1, 1896, 99 prisoners out of 800 had been caught by the disease, this ratio fell gradually from 84 to 13 during the next month when the prisoners received Sumatra rice instead of Saigun rice.

A Pernicious Fever, presumed to be of malarial origin and said to be more deadly than cholera, is ravaging Fashkand, a city in Central Asia, situated in a fertile plain. Numerous gardens and vineyards are interspersed among the mud-built and reed-thatched houses. The fever has raged there for four years and leaves the survivors unfit for work. The disease is spreading throughout Russian Turkestan and Merv.

Sanatoria for Consumptives.—Professor Leyden considers it the duty of society to provide sanitoria where patients can be sent in the early stages and restored cured to their families. One-third are cured and one-third show marked improvement in the sanatoria already established and it is merely a question of increasing the number and bringing them within the reach of the middle and lower classes. He states that the fact is established that pure air is the chief essential and that this can be obtained in the country where the patient habitually resides, disproving the necessity of sending him to a distance and avoiding the dangers of a return from a warm to a colder climate. The King of Sweden has given the 2,200,000 kroner presented to him on his twenty-fifth jubilee to found sanatoria for phthisics in Sweden.

Prophylactic Hygienic Measures in Barber Shops.—The Paris authorities have distributed a circular among the barbers and hair dressers of that city containing directions for disinfecting their instruments, etc. It recommends that metal combs be substituted for ivory, etc., and that they should be immersed in boiling soapy water immediately after being used, while the razors, brushes, scissors, etc., should be placed for half an hour in an oven heated to 100 degrees C. or in an air-tight box over a solution of 50 grams of formic aldehyde and 200 grams of salt. Rice powder should be applied with a dry spray or bellows. The hands should be washed with soap before passing to another client and the floor sprinkled with moist sand when cutting hair, which should be swept up at once and all burned together at the close of the day.—*Revue Médicale*, October 20.

Value of Street Sweepings, Garbage and Sewage.—The Secretary of Agriculture has authorized an investigation of the extent of the use of these materials as fertilizers in this country, the results that have attended their use and the best method of applying them to the soil. It is a well-established fact that where sewage must be turned into a stream it is better that it first be allowed to percolate through a layer of soil, the soil being either a specially prepared filter bed or only an ordinary farm, with or without underdrainage. Opinions as to the extent of the danger of disseminating pathogenic organisms among men and animals by the use of sewage for the irrigation of field and garden crops will be of value to the Department. Knowledge of any evidence of the spreading of diseases in this manner and date concerning published reports of such may be forwarded to H. W. Riley, U. S. Department of Agriculture, *Division of Chemistry, Washington, D. C.*

A New Sanitarium for Incurables in New York.—Buildings are being erected in Forestburg, N. Y., by the Sisters of St. Dominick to be used as a sanitarium during the summer season for patients from St. Catherine's Hospital, Williamsburg, Long Island, and as a permanent home for incurables. The site is 1,947 feet above the sea level. Patients in the first and second stages of phthisis will be received in order that they may have the benefit of the high altitude. The estate covers an area of 1,173 acres and the various buildings are separated from each other by a distance of from 1,000 to 3,000 feet. The architecture is of medieval monastic style and the buildings will be provided with all modern improvements, heated by steam and lighted by electricity. When completed the establishment will be the largest of its kind in the United States.—*Medical News*, October 23.

An Antitoxin Circular of a State Board of Health.—The Massachusetts State Board of Health has found it necessary to remind physicians of the reciprocal duties they are expected to perform in return for the furnishing of antitoxin facilities for the bacteriologic diagnosis of diphtheria, etc., by that body. In a circular recently issued they are reminded that the antitoxin is furnished gratuitously, to be used in the cases of persons unable to pay for it, and on condition that a description of the case and the effect of the remedy be furnished the Board of Health in return. The State Board of Health will withhold future supplies of antitoxin from local boards which fail to secure compliance with this rule. Care in the storage and distribution of antitoxin are also enjoined upon the local board, and instructions in the use of the diphtheria culture tubes are given. With regard to the examination of sputum, the State Board will receive for examination only specimens forwarded in the receptacles furnished by the board. Leaky receptacles endanger all persons who handle them. Material sent by mail will be rejected. Cover-glasses for the examination of blood with reference to malarial infection, with instructions for their use, will be sent on application, to any part of the State. Examinations of cultures, sputum, etc., will be made gratuitously by the Board's pathologist, if the conditions of transmission are complied with, and not otherwise.

New Argentine Law in Regard to the Sale of Medicines.—The Congress of the Argentine Republic is expected to pass a law creating a national board of health (or Department of Public

Health, as it is called officially). The law will become effective in a short time. This board of health will have complete control as to what medicines or compounds shall be allowed upon the Argentine market, as will appear from the following two articles of the law:

> Article 36.—It shall be lawful to sell or to expose for sale in any pharmacy or apothecary's shop or store such specialties or compounds only whose component parts are clearly specified upon a visible part of the package thereof, setting forth also the doses of the active substances contained therein.
>
> Article 37.—The Department of Public Health will authorize the sale of the medicines referred to in Article 36, when the required conditions have been fulfilled, without which authorization such goods can not be offered for sale.
>
> Failure to comply with the requirements of these two articles will be punished by a fine of from $100 to $200.

It will therefore become necessary for American manufacturers exporting medicinal compounds and specifics to the Argentine Republic to obtain the required permit from the Department of Public Health and to state the composition of the medicine on each package. Full information concerning the further requirements for securing the above permit will be supplied upon application to the editors of this paper.—*Scientific American*, October 30.

The Tracadie Lazaretto.—The Canadian lazaretto in Tracadie, Gloucester County, N. B., is finely located. It is on the shores of the Tracadie River, overlooking the Bay of Chaleur, which is part of the Gulf of St. Lawrence. It is very different from the pestiferous island of Molokai or the open sepulchres about Jerusalem in which the Scriptural lepers had their abodes. But circumstances were not always so favorable for the poor lepers at Tracadie as now. At that time the lazaretto was so badly kept that the lepers tried to remain in concealment among their own families as long as possible. On being discovered they were lassoed and dragged or driven with long poles to the lazaretto, where men and women were indiscriminately herded together. The lepers' food was placed on the ground, and they helped themselves to it as best they could. One of the Sisterhood of the Hotel Dieu, in Montreal, heard of the pitiable condition of the Tracadie lepers, and volunteered to start a mission among them. She induced the government to build a new lazaretto, and she was placed in charge of it, having several other sisters under her. The lazaretto is a fairly commodious building, partly of logs and partly of planks, and, while hardly conforming to our idea of what a government building for this purpose should be, it is kept scrupulously clean, while the inmates are well fed and well cared for. There is a small farm which the lepers cultivate, and they also own boats, from which they fish. Tracadie itself is a small settlement of log huts. The population is chiefly French Canadian, and the families are large and badly crowded. Various stories are told of the origin of the disease in Tracadie. One says that 140 years ago a Syrian bark was wrecked near that place, and some of the crew, who were affected with leprosy, remained in Tracadie and married there—G. H. Fox, M.D.

Yellow Fever.—The anticipated betterment of the yellow fever condition from the cold wave prevalent in the fever district, at the closing of our last report, was tardy. The dispatches are as follows: November 3, New Orleans, 5 deaths and 39 new cases; Montgomery, Ala., 1 death and 7 new cases; Memphis, 1 death. November 4, New Orleans, 7 deaths and 40 new cases; Mobile, 1 death and 11 new cases; Edwards, Miss., 2 new cases; Nittayuma, 1 new case; Bay St. Louis, 5 new cases; Montgomery, 1 death and 2 new cases; Biloxi, 6 new cases; Scranton, 2 new cases; Memphis, 1 death and 3 new cases. November 5, New Orleans, 10 deaths and 31 new cases; Cayuga, Miss., 1 new case; Memphis, 1 new case; Mobile, 1 death and 11 new cases; Montgomery, 1 death and 2 new cases; Whistler, Ala., 2 deaths. On November 4, Dr. Olliphant, President of the Louisiana State Board of Health, promulgated the following order, to take effect immediately: Quarantine against all points is raised, except that passengers from Mobile, Montgomery and coast points coming to New Orleans will be required to have certificates from health officers or from reputable physicians, that for ten days past there has been no yellow fever in house where such passengers have resided. And it will further be required that all baggage and household effects from these points be disinfected at the Rigolets station under supervision of quarantine officers. The Mayor of Birmingham, Ala., also raised quarantine against all yellow fever infected points, and on November 5, the Southern Pacific Railroad Co. reopened their "Sunset Route" for through business to New Orleans. November 6, New Orleans, 5 deaths, 23 new cases; Memphis, 1 new case; Mobile, 1 death, 5 new cases; Montgomery, Ala., 3 new cases. November 7, New Orleans, 7 deaths, no report as to new cases. November 8, New Orleans, 7 deaths, 14 new cases; Mobile, 2 deaths, 4 new cases.

An Epidemic of Cerebrospinal Meningitis.—Francis H. Williams, M.D., reports briefly concerning his experience at the Boston City Hospital with an epidemic of cerebrospinal meningitis during last winter and spring. The first case entered the hospital Dec. 30, 1896. The records of the hospital from 1880 to Dec. 30, 1896, include thirty-nine cases, with a mortality of 59 per cent. From the latter date to June 1 there have been forty-seven cases, forty-two of which entered in March, April and May; that is to say, during the past five months there have been more patients with this disease in the hospital than in the previous seventeen years. The tabulation of these forty-seven cases by localities, shows that one part of the city has not been more affected than another. The patients have been youths and adults; and the form of the disease has been very severe. It has been characterized by sudden onset, with an average duration of about thirteen days in the fatal cases, and the very high mortality in the forty seven, the whole number of cases, of a little over 72 per cent. The prominent symptoms have been intense headache, delirium, a stiffness of the muscles of the back of the neck, retraction and stupor; in some cases there have been diplopia, strabismus, deafness and vomiting; in eleven cases herpes labialis; in seven cases some form of eruption, but this does not justify the name of spotted fever, which is sometimes given to this disease. In twelve cases a blood count was made and in most of these there was leucocytosis. The serum test for typhoid fever was tried in eight cases and found to be negative in all. Lumbar puncture was done in thirty-two cases, and judging from these this puncture does no harm and it readily establishes the diagnosis when fluid containing pus and organisms is found. "In the seven cases in which I performed the operation it yielded a positive result in all. The operation, under strict antiseptic precautions, is readily done by using a small trocar to tap the sac surrounding the spinal cord and draw off some of the fluid; the point of insertion is between the third and fourth lumbar vertebræ. I have usually chosen a point slightly lower than the lowest part of the spinous process of the second lumbar vertebra and one inch outside of it, and inserted a small-sized trocar, somewhat downward and inward, to a depth of rather more than two inches. I have always used a trocar instead of a needle, as the latter is liable to be bent or broken off and is too small to allow the thick pus that is present in some cases to flow through it easily. The lumbar puncture is very serviceable for diagnosis, as often there is no history and the symptoms may be few. It may also relieve pressure temporarily. That there is pressure is shown by the fact that the fluid is apt to squirt out at first with some force, and sometimes two ounces may be readily withdrawn. The diagnosis has been established in more than one-half of these forty-seven cases, either by examination of the fluid obtained by lumbar puncture or by autopsy. The present treatment of the disease is wholly unsatisfactory, but the fact that we have the means of making an early diagnosis in many cases, and that the organism is not a robust one and seems to be short-lived in the body, offers the hope that better treatment may soon be found."

Increase of Insanity in England.—A letter in the *American Practitioner and News* contains the following data bearing on the increase of accommodations required for the great City of London:

> "During the year 1896 the Asylums Committee of the London County Council was responsible for 13,526 persons of unsound mind as compared with the 10,104 in 1890; or an apparent increase of 33 per cent. in six years. Pending the com-

pletion of a new asylum at Bexley Heath, 600 beds have had to be provided in temporary buildings at Banstead and Colney Hatch, and like accommodation for 400 female patients is in progress at Hanwell. Last month an estate of 1,060 acres was purchased for $200,000, on which a seventh county asylum will be erected for 2,000 beds. The weekly rate for maintenance remains at $2.55 per week per patient, chargeable to parishes and unions in the county. The pathologic laboratory at Claybury is fully equipped, and arrangements have been made whereby clinical instruction can be given to students from four of the London medical schools. The English statistics are not always so kept as to allow very exact inferences to be drawn from them; but we notice that where the effort has been made to sift out the old cases, the increase in new cases is apt to be greater than where the traditional way of reporting 'first admissions,' which may be of persons insane for twenty years, is followed. In the County of London, where only the 'new names' are computed for five years, the actual gain in these first admissions was 711 from January 1892 to January 1896, a gain of 28 per cent. in five years, or much beyond the gain in population. The officials giving these figures, however, wish to make certain allowances (which may or not be required), after which, they say, 'it will be found that occurring insanity has not increased so greatly out of proportion to the population as appears at first sight.' This may very well be true, since no one acquainted with the facts believes that there is a rapid gain in new cases of insanity beyond what the gain in population would require. But there is no other way for accounting for the very steady and now enormous increase of new cases. Thus the proportion of registered insane to population, which was but 18.67 in 10,000 in 1859 (one in every 535), was in 1896, 31.38 in 10,000 (one in every 319). Here there was a large gain in the whole population, though much less than the gain among the insane. But in counties where population has been losing, and in whole countries, like Ireland, where this is so, we still see a gain in the new admissions of the insane. Thus in Nottingham, where the population in ten years (1886 to 1895) fell off more than 6,000, or 2.5 per cent., the yearly insane admissions went up from 100 to about 150. The first requirement for statistic accuracy in this matter, which excites increased interest everywhere, is to compute carefully the first attacks, as distinguished from old or relapsed cases. Until this is done for some considerable area of country, where the population is reasonably permanent, great cities showing a disproportionate increase, for several reasons, the labor of investigation among discordant and incomplete statistics will hardly furnish a basis for inference of any value."

NECROLOGY.

Charles M. Roth, M.D., New York City, October 27, aged 72 years. He was born in Giessen, Hesse-Darmstadt, Germany, and was graduated from the university there in 1852 as Doctor of Philosophy. He came to America in 1860 with the intention of occupying the Chair of Chemistry in Irving College, Manchester, Md., which position he had obtained through his friend and teacher, the celebrated Dr. Just. von Liebig. He attended the lectures at the College of Physicians and Surgeons and received his diploma from that institution in 1866. He contributed many articles on medical science to German and English periodicals, and was a frequent contributor to the *New York Medical Record*. He was recognized as an authority on gynecology, and was a member of the County Medical Association.

Sir Rutherford Alcock, K.C.B., D.C.L., F.R.C.S., Nov. 2, aged 80. Sir Rutherford was on the medical staff of the British auxiliary forces in support of Isabella II. against the Carlists and in Portugal in support of Marie II. against the Miguelists. For his services in the peninsula he received honors, and a number of decorations from the English, Spanish and Portuguese governments. In 1844 his government appointed him consul at Foochow. Two years later he held a consulship at Shanghai and in 1858 took the same position at Canton. He was then sent as minister to Japan. He was created K.C.B. in 1862. In 1865 he was transferred to Pekin as chief superintendent of trade in China remaining there until 1870. Some of his books are "Notes on the Medical History of the British Legion in Spain," 1838; "Elements of Japanese Grammar," 1861; "The Capital of Tycoon," 1863, and "Familiar Dialogues in Japanese," in 1878. In 1876 he was president of the Royal Geographical Society, and presided over the health department of the Social Science Congress held in 1882.

M. Roony, M.D., who died at Quincy, Ill., September 10, (*vide* Journal, p. 660) aged 60 years, was a graduate of the Miami Medical College, 1866, and of the Long Island Medical College, 1874. He practiced in Quincy from 1871 and was physician to St. Mary's Hospital and many other Catholic institutions in that city. He was a member of the Adams County Medical Society and at one time its president. His death was due to perforation of the ileum at the site of a band of adhesion which obstructed the bowel.

Charles Anson Fox, M.D., College of Physicians and Surgeons, New York, 1881, disappeared May 17, 1896, after having gone out for a short walk. His home was in East Hartford, Conn., where he had retired a few years ago owing to mental trouble. On October 31 last his body was found buried in about three inches of leaves in the woods on the road to Bolton, Conn., 300 feet away from the highway and about one mile east of Manchester Green. The clothing and flesh crumbled from the skeleton, but a gold watch, an Odd Fellow's pin and a memorandum book established its identity. There were no indications of suicide or foul play.

Joseph Edwin Culver, M.D., College Physicians and Surgeons, New York, 1849, who was born at Croton, Conn., Feb. 9, 1823, died at his home in Jersey City, N. J., November 1. He had been treasurer of Hudson City for some length of time, up to the consolidation of the cities mentioned, and was one of the organizers of the Hudson County (N. J.) Medical Society, besides having held the superintendency of the public schools for a number of years.

Frederick L. Braun, M.D., Cleveland, Ohio, October 31, aged 51 years. When the Civil War broke out he enlisted in Company A, West Virginia Cavalry and served three years, receiving an honorable discharge. He then entered the medical department of the University of Pennsylvania. His record there warranted a post-graduate course at Heidelberg. Dr. Braun practiced at various times in Pittsburg, Toledo and Cincinnati.

George F. Matter, M.D., Jefferson 1866, of the Two Hundred and Tenth Regiment Pennsylvania Volunteers and a hospital steward during the war, died at Shenandoah, Pa., of cerebro-spinal meningitis, October 22, aged 57 years.

Charles Hudson Avery, M.D., Long Island College Hospital 1865, for many years secretary of the New York County Medical Society, died at his home in the Borough of Manhattan, N.Y., November 3. He was born in 1834 in Perryville, N. Y., and had been for thirteen years an invalid. A widow and a daughter are his survivors.

Frank L. Sallade, M.D., Jefferson 1866, at Womelsdorf, Pa., October 24.——Arthur L. Hummel, M.D., University of Maryland 1884, of Hummelstown, Pa., medical journalist, at Denver, Colo., October 26, aged 40 years.——A. H. Ayres, M.D., Urbana, Ohio, October 31, aged 65 years. The Doctor was formerly superintendent of the Columbus Insane Asylum, and during the Civil War he served as surgeon of the Thirty-fourth Ohio Volunteer Infantry.——Isaac D. Conrad, M.D., Newton, Kan., October 26.——W. D. Cooper, M.D., Morrisville, Va., October 29, aged 77 years.——George W. Langford, M.D., Williamston, Mich., October 28, aged 57 years, a graduate of the medical department of the State University.——Elijah R. Mendenhall, M.D., Indianapolis, Ind., November 3, aged 82 years.——Louis Meyer, M.D., Cleveland, Ohio, October 29.

SOCIETY NEWS.

The Indian Territory Medical Association will hold its semi-annual meeting at Muskogee, I. T., Dec. 7 and 8, 1897.

The American Electro-Therapeutic Association will hold its next annual meeting in Buffalo, N. Y., Sept. 13, 14 and 15, 1898.

Tri-State Medical Association.—Owing to the quarantine now being enforced against Memphis, which will hold at least ten days after the first killing frost, the meeting of the Tri State

Medical Association has been postponed until December 15 and 16.

The Association of Military Surgeons of the State of Illinois held its annual meeting at the Great Northern Hotel, Chicago, November 4. The following officers were elected: President, Col. Nicholas Senn; vice-president, Major Truman W. Miller; secretary and treasurer, Major Charles Adams. A banquet in the evening ended the session. Colonel Senn acted as toastmaster.

The Medical Association of Central New York opened its thirtieth annual convention at Buffalo, N. Y., October 19, with an attendance of about one hundred physicians. The discussion of greatest general interest was that on "The Value of Expert Testimony in Medico-Legal Cases." Tracy C. Becker, a lawyer, presented the argument from a legal point of view and read opinions from many judges of the supreme court of this State. All the judges admitted the necessity of expert testimony, but agreed that the present system of obtaining it made it worse than valueless. The report of the Committee on Remedial Legislation in regard to expert testimony was in favor of a change of the statutes to require all medical testimony to be brought in by a commission to examine the subject and the matters to be brought to the jury in the trial, the medical experts being appointed by the court as referees, and are to be paid by the county, without being allowed to receive fees from either the defence or the prosecution.

MISCELLANY.

The Western Medical and Surgical Gazette, Vol. i, No. 1, November, 1897, has come to our exchange table. The editors of this new journal are Wm. N. Beggs, A.B., M.D., and Lincoln Mussey, M.D., and the office of publication, Denver, Col. The *Gazette* will appear monthly. Subscription price, $2 per year.

Hemotherapeutics in Chlorosis.—De Dominicis considers a form of diabetes affecting principally the red corpuscles. He treats it with the usual tonic regimen or with the direct transfusion of blood from a dog, with which he has secured remarkably favorable results. No benefit was derived from venesection.—*Therap. Woch.*, October 1.

Disinfection of the Conjunctiva.—Albin Dalen reports in the August *Nordiskt Med. Arkiv*, the results of much experimental research in this line. He asserts in conclusion that the disinfecting power of the physiologic salt solution is fully equal to that of sublimate in disinfecting the conjunctiva; also that bacteria continue to proliferate beneath a bandage moistened with 1 to 5,000 sublimate, and that it has no possible advantage over a dry sterile bandage; also that the introduction of iodoform has no perceptible effect upon the development of the microbes.

Extirpation of a Fistula in the Neck through the Mouth.—Professor Hacker describes in the *Cbl. f. Chir.*, of October 16, his extirpation of a complete congenital fistula in the right side of the neck of a boy of 8 years, leaving only a slight lineal scar. The fistula allowed the passage of milk, which appeared in the throat between the right tonsil and the arch. He found the canal easily movable its entire length, and by inserting a fine silver wire through the fistula with a hook in the end and a thread he succeeded in pulling the entire canal loose and drawing it out in two parts through the mouth like the evulsion of a finger of a glove.

Highly Decorated.—According to a secular exchange, Sir William MacCormac, president of the Royal College of Surgeons in London, is well recognized. He has the Order of Medjidie, the Crown of Prussia, the Ritter Kreuz of Bavaria, the Dannebrog, the Crown of Italy, the Cross of the Takavo of Servia, the Order of Merit of Spain and Portugal, and the Star of Sweden. He is also Knight of Grace of the Order of St. John of Jerusalem. Sir William was born in 1836, has taken part with the volunteer medical corps in the Franco-Prussian, Turko-Servian and Russo-Turkish wars. He is an enthusiastic fisherman and golf-player.

For the Benefit of Dr. Laporte.—A subscription has been started for the benefit of Dr. Laporte by the medical journals of Paris, which have been most emphatic in their denunciation of the arrest and criminal proceedings instituted against this young physician. He is one of the medical men on the night service furnished free to the poor, and was summoned hastily to a confinement case which he found complicated with a deformed pelvis, but as it appears, the patient had already borne five children. Natural delivery being difficult and the child already dead, he performed craniotomy with a cold chisel, wood mallet and a mattress needle, not leaving until delivery had been accomplished. Peritonitis developed later and death ensued. At the necropsy the bladder was found to have been perforated in two places. He was arrested and condemned to three months imprisonment.

A Death by Football Play.—The death of a New York football player, from a broken back-bone received while the game was in progress, will revive the discussion of the dangers of this game. It is true, the accident was the result of violence, but it is so unusual that it is hardly fair to draw any sweeping conclusions from it. It has been asserted that the young man had some kind of structural weakness of the vertebræ and did not know it. The doctors say that the fracture was caused by a sudden thrust of the head forward, the bone snapping in consequence, but they admit that the same result would probably not follow once in a thousand times. An abnormal brittleness of the bones is a possible condition, and the moral of the case is that young men who play football should be thoroughly acquainted with their physical condition.

Progress at Craig Colony During the Past Year.—The Craig colony for epileptics at Sonyea, Livingston County, N. Y., closed its fourth fiscal year Sept. 30, 1897. There were at that time 214 inmates in the colony, the majority of whom had been transferred from the various county houses throughout the State. New buildings are in course of construction which, when completed, will enable the colony to accommodate 140 additional patients, making the total population about 350. It is estimated by State charity officials that this number represents about one-third of the total number of epileptics now on public charge throughout the State. The medical superintendent, Dr. William P. Spratling, reports a great increase in the value of agricultural and industrial products of the colony over last year, so that the ratio of earnings of the patients to the cost of their maintenance is even larger than that of last year, which was a little over 50 per cent. A laboratory for the use of a pathologist and pathologic chemist is being constructed. Dr. Christian A. Herter of New York has been appointed pathologic chemist and Dr. Ira Van Gieson of New York consulting pathologist to the colony. Dr. Frederick Peterson of New York was re-elected president of the board of managers. The managers, at their annual meeting, decided to ask the coming legislature for $200,000 for dormitory buildings in order that they may increase the residence capacity of the colony for patients.

Unreliability of our Present Bacteriologic Tests in Diphtheria, is emphasized by Prof. Spronck in a contribution to the *Semaine Méd.*, of September 29. He states that macroscopic and microscopic examination of colonies developed in serum is not absolute, and that nothing but the inoculation of an animal will decide the question positively, except in the severest cases or during epidemics. W [illegible] ous injection of 2 c.c. of fresh culture in b [illegible] ing 300 grams, but only causes a more or less marked edema, the bacillus has nothing in common with the diphtheria bacillus except a superficial resemblance in the vast majority of cases. Absolute certainty can only be attained by a previous preventive inoculation of 0.5 to 1 c.c. of active antidiphtheria serum at 1 to 10,000 injected under the skin of the inside of the thigh of a guinea pig weighing about 300 grams. Six hours later this animal and another of the same size, are both inoculated with 2 c.c. of the culture, in the abdomen. If the bacillus is the true diphtheria bacillus, the immunized animal will show no traces of edema, but if not, both animals have edema. The test does not require more than twenty-four hours if the materials are at hand. By thus scientifically eliminating all pseudo-diphtherial cases, we will only have to resort to serum treatment where it is actually required. He adds that the preliminary immunization will not be necessary if the result of his recent research is confirmed, that the attenuated diphtheria bacillus can not live in the human organism.

The Antivivisection Bill.—The following letter was recently sent to every county medical society in Indiana, in response to request made in the article on "Antivivisection" in the Journal of Aug. 14, 1897: "At a regular meeting of the St. Joseph County Medical Society, a committee was appointed to draft resolutions, disapproving U. S. Senate Bill 1063, instigated by the antivivisectionists, now on the Congressional Calendar, for the next session. The committee was instructed to correspond with the local Congressmen and the United States Senators of Indiana, urging them to refuse their support of the above bill. The committe was furthermore instructed to send a copy of the resolutions to the Congressmen and the United States Senators and also to advise every county society in the State of the action of the St. Joseph County Medical Society urging them to take a similar stand on this important question. The committee would be pleased to learn the attitude of your Society concerning this bill, also to know what action taken.

Yours fraternally, H. F. Mitchell, Secretary.
South Bend, Ind.
J. B. Berteling, H. T. Montgomery, F. P. Eastman, Com."

Anatomic Changes in Eclampsia.—A study of 500 cases by Prutz, a large proportion personal, shows that hemorrhage is the distinguishing feature of the changes found in the various organs and that among the complications bronchopneumonia and cerebral hemorrhage are the principal causes of death. Bacteriologic investigation results negatively except in mixed infection. Chemic investigation of the blood and of the toxicity of the urine and serum is still in the preliminary stages, and our present knowledge of eclampsia does not justify sweeping conclusions in regard to its etiology. In 368 cases only seven had sound kidneys (these not certain); there was nephritis in 46 per cent.; chronic inflammatory processes in 11.6 per cent. Changes in the liver mostly hemorrhagic, were noted in 213 cases. Cerebral hemorrhage into the brain was noted in 28.4 per cent.; intracranial, 35.3 per cent. The stomach, intestines, spleen, pancreas, suprarenals and genitalia are also frequently found to have been the seat of hemorrhage, and even the skin, mucous membrane, muscles, serous surfaces and the thyroid gland.—*Deutsche Med. Woch.*, September 30.

Celloidin Threads for Sutures.—A fine, solid thread that is flexible, ties easily, does not knot, and is inexpensive, is made by boiling pieces of hemp or linen thread in a soda solution, rinsing in cold water, and boiling them twice again at an interval of six to eight hours, five minutes at a time, in ordinary water, dipping them afterward in alcohol and drying. The threads are then rolled on glass spools and immersed for twenty-four hours in a mixture of equal parts alcohol and ether, with 25 to 30 per cent. celloidin and 1 per cent. sterile castor oil. The thread is then wound on a wooden frame and the excess of celloidin removed, after which it is wound on the spools, and sterilized just before the operation by boiling it twice in a 1 per cent. solution of sublimate. It is made to resemble silkworm gut by impregnating it again with celloidin until it is the required size, treating it the last time with a 5 per cent. solution of celloidin. De Goubaroff adds that it does not act like a drain, which is one of the disadvantages of silk.—*Sem. Méd.*, October 6.

Gleanings.—St. Vitus dance cured with massage, combined with baths at 27 degrees R. and iron-arsenic medication 10 cases—(*Wratsch*, August 14).——Clamp forceps recommended instead of a ligature for the funis neonatorum, applying them perpendicularly, close to the umbilicus, and leaving them in place for twenty-four hours, wrapped in cotton. Bar claims superior results by this simple and certain method.—(*Presse Méd.*, September 8).——Nineteen cases of Madura foot successfully treated by stretching the nerve. Nine observations of zona as premonitory symptoms of tuberculosis.—(*Ann. de Derm.*, September.)——Tendency of wounds in the stomach to heal spontaneously. Expectant treatment advised unless alarming symptoms occur.—(*Gaz. d. Osp. e d. Clin.*, September 28.)——Band iron recommended for bandages instead of plaster casts, in military compaigns.—(*Münch. med. Woch.*, No. 33.)——Euchinin recommended, especially for children; "harmless, tasteless and as effective as quinin."—(*Gaz. d. Osp. e d. Clin.*, October 3.)——Remove the odor of iodoform from the hands by rinsing them in orange-flower water.—(*Sem. Méd.*, September 29.)——The remarkable attenuation of syphilis in the hot dry belt of Mexico noted by Carbajal.—(*Revista Médica*, September 15.)——Another medical saint added to the calendar by the Pope: Anthony Zacaria, Pavia, 1520. The other physicians already on the calendar are St. Luke, Cosmo and Damien.——A course of training for disinfectors inaugurated at Breslau by the Prussian government in charge of Professor Flügge.

Surgery of the Kidneys.—Israel leads in the number of operations performed on the kidneys to date, 191, with a mortality of 20 per cent. in 79 nephrectomies, although his mortality in 24 cases of malignant neoplasms was only 12.5 per cent. Seven relapsed of the 21 cured at first, but the rest, 60 per cent., have shown no signs of relapse in three years. He ascribes this progress to improved diagnosis by palpation and cystoscopy and the extirpation of the adipose capsule and glands. He disproves of exploratory incisions unless strictly indicated. Küster states that palpation is insufficient when the tumor is in the center or at the upper pole, and may lead to metastasis. *He distinguishes three groups of malignant neoplasms: Carcinoma*, a late palpable tumor on the borders of the organ, early breaking through the capsule, hard to move; *sarcoma*, occurring principally in childhood, forming large tumors early, breaking through the capsule late, with only inflammatory adhesions; *struma suprarenalis*, usually leaving one pole intact, but may remain stationary for years and then develop suddenly, very malignant. *In obscure cases open up the kidneys freely on both sides.* Easily movable tumors can be removed through a lumbar incision; those harder to move should be reached by a laparotomy, and those absolutely fixed should not be operated on. Tuffier reports 156 surgical interventions on the kidneys. He agrees with Israel that wandering kidney is only a symptom of complex enteroptosis and performs very few nephropexies for this cause. He advocates extreme conservatism in traumatic lesions and performs nephrectomy early *in primary tuberculosis (fifteen cases) to avoid a later operation.* He has treated intermittent hydronephrosis most successfully with nephropexy. Küster states that the mortality in the 263 operations on record for malignant neoplasms of the kidneys is 41 per cent., but of the 155 patients that survived only 9 are permanently cured, that is, without recurrence for more than three years.—Moscow Congress.

Recovery Allowed for Injuries Sustained before Birth.—A novel question was decided by Judge Chetlain of the superior court of Cook County, Illinois, Sept. 24, 1897, in the case of Allaire v. St. Luke's Hospital. The question was whether a child after it is born has a right of action for injuries sustained by it *en ventre sa mère*; or, in other words, whether a child unborn is a person in being, so as to be entitled after its birth to maintain such an action. It was averred that the defendant was in the business of conducting a hospital and of accepting for accouchement for hire, women about to be confined; that the mother of the plaintiff, three or four days before his birth in the regular course of nature, applied to the defendant and contracted with it, upon a compensation then and there agreed on for it, for the latter to shelter, attend, treat during confinement and care for her and her child, then *en ventre sa mère*, during the period of childbirth and convalescence thereafter; that in pursuance of that agreement the mother paid such compensation, and was accepted at the hospital; that the servants of the hospital then and there placed her in an elevator for the purpose of taking her and the unborn plaintiff to an upper floor of the hospital for shelter, care and treatment, and that such servants so negligently and unskilfully conducted and operated the elevator that the plaintiff was permanently injured. The question of law applicable to the facts of this case does not appear to have ever been decided, either in this country or in England. From a careful study of such authorities as he could find bearing at all upon it, the judge came to the conclusion that, as a general principle, the child *en ventre sa mère* is considered as born or *in esse* when it is for its benefit, and especially so when the application of the doctrine will work no hardship. He further thinks that the rule should be applied in personal actions: 1. Where a person inflicts an injury upon a woman with child, knowing her to be such, and for the purpose of inflicting an injury upon her unborn child, whereby such child suffers permanent injuries. 2. Where a mother or other person contracts, upon a valuable consideration for, in reference to, or on behalf of the unborn child, for care and attention or other service for the benefit or safety of the child, or of both the mother and child, where the duty arises out of contract and from the relative situation and circumstances of the parties at the time of the occurrence of the acts of negligence. So, here, the judge holds that there was a good cause of action stated.

Hospitals.

PENNSYLVANIA.—The D. Hayes Agnew Memorial Pavilion of the Pennsylvania Hospital, Philadelphia, held its opening ceremonies October 15. It was erected at a cost of $150,000, is 154 feet in length and 184 feet in depth, and is furnished with the latest surgical instruments. A feature of the third floor is a private room with a wainscoting of mirrors for optical cases. The new building has 120 beds.

BY THE WILL of the late George M. Pullman the following bequests were left to hospitals: St. Luke's Hospital, $20,000; Hospital for Women and Children, and Presbyterian Hospital, each $10,000.——The new hospital at Niagara Falls, N. Y., was opened October 30, with appropriate ceremonies.

Societies.

The following meetings are noted:

Illinois.—Peoria City Medical Society, October 28.——The Springfield Medical Club, October 27.

Indiana.—Annual meeting of the Big Four Railway Surgeons, Indianapolis, November 11.——Cass County Medical Society, Logansport, October 29.——St. Joseph County Medical Society, South Bend, October 27.——Tippecanoe County Medical Society, Lafayette, November 10.

Kentucky.—Southern Kentucky Medical Association, Bowling Green, November 3 and 4.

Massachusetts.—Union Medical Society, Springfield, October 29.

Minnesota.—Hennepin County Medical Society, Minneapolis, November 1.

Missouri.—St. Louis Medical Society of Missouri, St. Louis, November 6.——Southern Surgical and Gynecological Society, St. Louis, November 9, 10 and 11.

New York.—Academy of Medicine, Syracuse, October 26.——Suffolk County Medical Society, Patchoque, October 28.

Detroit.

THE HEALTH REPORT for the week ending November 6 is as follows: Deaths 85, of which 30 were children under 5 years of age; births 42, of which 35 were females; 30 cases of diphtheria, 46 cases of scarlet fever; deaths from diphtheria 4; scarlet fever none.

AT THE REGULAR MEETING of the Wayne County Medical Society October 28, Dr. S. E. Sanderson read a paper on "Asepsis in Barbering." The writer said: "What barbering is today, practically, barbering always has been. True, the styles of hair and beard may change, but the barber's methods never. And what a source of contagion these methods must be! What eager crowds of malevolent pathogenic bacteria must lurk within the folds of his towels, between the teeth of his combs and on the blades of his scissors and razors! What an opportunity for the streptococcus of erysipelas to enter the *locus minoris resistentiæ*, as the incision from a barber's razor! The micro-organisms of furuncle would rejoice at such an opportunity, while the bacillus of anthrax would consider itself highly favored with such a field for propagation. Would any of us run the gauntlet of menace from such diseases as tinea, scabies or phtheiriasis by putting ourselves unreservedly into the hands of a barber in one of our third-rate shops? Yet every time we commit ourselves to the tender mercies of even our best tonsorial artists, we face the possibilities of becoming inoculated with syphilis or lupus, and we can not say when we are free from infection of favus, trichophytosis, impetigo contagiosa, and even carbuncle, glanders, leprosy, diphtheria, smallpox, and in fact any contagious disease. True, these last named diseases are rarely if ever so contracted, but even so, what one of us can say he shall therefore be fortunate enough to escape. Barbering as it is practiced today is a menace to the public health. A process like barbering, which is so often attended with an opening of the cuticle with an edged tool, should be done under conditions which make it certain that such tool and the surroundings of such a wound will not prove a source of infection. In other words, we should have aseptic barbering. The sanitary authorities of Paris have taken action in this matter and have instituted regulations to require barbers to use aseptic tools and sterilized towels, and to keep their hands clean by washing for each customer. A later report from France says that these regulations are rigidly enforced, as the new law has already brought down the penalty upon at least one offender. What shall we do in this matter? There is only one right course. France has taken the initiative step; America should not be slow to follow. Every barber should be required to use only such combs, scissors, razors and brushes as can be thoroughly sterilized by boiling or by the application of some antiseptic solution. Each towel or napkin should be used but on one customer, after which it should be thrown into the wash. The barber's hands should be kept scrupulously clean by being carefully washed before each sitting, and then dipped into an antiseptic solution. In addition to this, all dusting powders and other means of holding and spreading contagion should be abolished, and the face of the customer treated with some such mild solution as listerin. The lather, brush and soap should be rendered sterile also."

Louisville.

THE ANNUAL REPORT of the Board of Safety has just been submitted and contains some interesting matter. It calls attention to the fact that the death rate in Louisville during the past year was only 14.4 per thousand, the smallest within thirty years. In bringing about this state of affairs, three sanitary police were appointed during the year and assigned to duty at the health office, in addition to which the entire police force has acted in conjunction with it. The report states "there is but one thing wanted in this department to render its work more efficient, and that is the employment of an experienced chemist and bacteriologist, for whose peculiar work there is a large field, and such work would surely result in a still further reduction in our death rate." The salaries paid in the department of health are as follows: Health officer, $2,000; secretary of board of health, $420; physician in eastern and western district, $1,800; live stock inspector, $1,200; assistant live stock inspector, $900; incidental and emergency fund, $1,000; total, $7,320, which will show perhaps one of the smallest amounts allowed any health department of a city of the size of Louisville in the United States. Attention is called to the work of the City Hospital, with upward of fifty physicians and surgeons attending and twenty-two female and two male nurses. The hospital has now a modern ambulance service, which is run at a cost of $1,510 per annum. The total cost of the hospital is $40,510.65. The actual cost to the city for officers, repairs, employes and patients has been less than $0.48⅔; cost per diem for rations, $0.14½; daily average of patients 156, the largest in the history of the institution. In regard to the Home for the Aged and Infirm, the report says: "After four years of unremitting effort, we have succeeded in erecting a hospital for the sick and an asylum for pauper idiots for the use of this institution." This is a good work and the Home is in splendid condition. It is recommended that an elevator be erected as soon as possible, as at present the inmates are compelled to walk up and down three flights of steps several times a day. The institution is run at a cost of $21,800. A farm run in connection with the institution has had a splendid yield. There are 317 inmates, 279 white, 36 colored; there were 25 deaths during the year; the average cost for each person, per diem, 12⅓ cents. The nurses of the training school of the City Hospital receive $5 per month during their stay in the hospital and $75 at the time of their graduation. The city physician's report is as follows: Number of visits paid by the physician in the eastern district, 496; number of prescriptions, 1,726; number of visits paid by physician in the western district, 387; number of prescriptions filled, 432. It is recommended that the location and office hours of these physicians be placed in the daily papers as an advertisement at regular intervals so they will be the more accessible to those needing attention. The city dispensary is located at the City Hospital, all prescriptions for the poor being certified by the city physicians or the health officer and are promptly compounded, free of charge. There were 1,891 prescriptions filled during the year. The cost of maintainance of the Eruptive Hospital for the year was $2,908.52. This is strictly a smallpox hospital. At the morgue there were 71 dead bodies received; number claimed by friends, 8; number of bodies given to the medical colleges, as provided by law, 63. This institution is conducted by the Medical Department of the University of Louisville, free of charge to the Board.

BANQUET.—The physicians who contributed to the fund for the entertainment of the members of the Mississippi Valley Medical Association in this city October last, met at the Louisville Hotel around the banquet table, to celebrate this most successful meeting. It was a fitting wind-up of a most enjoyable occasion, and the expression of opinion was that the twenty-third annual meeting of the Mississippi Valley Medical Association would be remembered with the greatest pleasure.

KENTUCKY SCHOOL OF MEDICINE.—An important change has taken place in this institution, in its amalgamation with the Kentucky University, becoming its medical department. Formed as it was by a consolidation, completed at Lexington in 1865, of Transylvania University, chartered as a seminary in 1783 and organized as a university in 1799, and Bacon College organized in 1836, this institution has had an honored career of more than a century. The University comprises four colleges, each under the government of its own faculty, and an academy or preparatory department, in charge of a principal and assistant.

CHANGE OF ADDRESS.

Blech, G., from 119 Miami Ave. to 15 W. Columbia St., Detroit, Mich.; Boytam, J. E., from 97 E. 3d St. to 319 Broadway, Cincinnati, Ohio; Brown, D., from 40 E. 57th St. to 254 W. 54th St., New York, N. Y.

ADDRESS.

THE NEEDS AND RIGHTS OF OLD AGE.

Doctorate Address Delivered at the Commencement Exercises of the Hospital College of Medicine, McCauley's Theater, Louisville, July 1, 1897.

BY I. N. LOVE, M.D.

ST. LOUIS, MO.

In this old Kentucky home of oratory, where the very atmosphere is charged with eloquence, where every individual from the moment he is able to articulate until the time when he tenders his resignation to the Great Ruler, is able to speak with the rhetorical skill of a Demosthenes, where the cattle on a thousand hills give forth their lowing in sounds of melody, it would be an error on my part to attempt to speak to you in an off-hand manner. I have instead elected to present to you a few thoughts jotted down at my leisure regarding a subject which I trust will not prove uninteresting. The topic which I have selected is "The Needs and Rights of Old Age."

One that is not far removed from the middle mile-post of life in discussing "The Needs and Rights of Old Age," can surely not be charged with indulgence in "special pleading," as the lawyers would say, but since every one of us, if we live long enough, will be classed within the ranks of the aged, self-interest is not entirely eliminated from the argument, for at the rate that the mile-posts are speeding by in this life's journey of ours, it will be but a short time until we will all be either old or dead. The statement can not be denied that each individual born into the world, who dies from any other cause than simple old age, or a gentle drifting away from life in so easy a way as to in no manner suggest death, has not received his just dues. In other words a proper death is inevitable and just as natural and physiologic as birth.

At the present rate of advancement the time will soon come when no one need die before his allotted time, save by accident. When we realize that the bulk of those who die in the world to-day, in spite of the progress of the sciences, die before they are five years old, we can see how much is left undone, and we are safe in saying that if the laws of health were properly observed and there was a proper application of the definite knowledge that we now have, all of these deaths prior to the age of five years need not occur at all.

CARELESS LIVING INVITES EARLY DEATH.

More and more we are having impressed upon us the fact that various microscopic forms of life, known as microbes, are present in the world here, there and everywhere, seeking whom they may devour, and as time advances and investigation is more complete, we find more and more that many diseases, particularly in the early periods of life, are dependent upon these micro-organisms. It is pretty clearly established that not only are the infectious diseases to which children are peculiarly susceptible dependent upon special germs, but many others are now found to come under the head, notably tuberculosis, the great "white plague," the disease from which one-seventh of all humankind die, the plague which would make the "black plague" of the ancient régime turn pale with envy. And yet we must remember that every individual, of no matter what age, would be able to resist this invading army, and the diseases resulting therefrom would be unknown, were it not for the fact that the victims have invited the enemy by their own indiscretions. In other words, all would be safe, even against infectious germs, did they observe the rules of health and not develop in themselves susceptibility to attack. Commencing then at an early period of life we are safe in saying that the individual is rendered susceptible to disease in general, and incompetent to cope with the dangers that surround him, only on account of not having husbanded his resources. By errors of diet, improper clothing, and the failure to correctly regulate the heat of the body, conditions are developed which invite disease and death, so we are safe in saying emphatically that from the beginning did we all eat proper food at the proper times in the proper way, and properly clothe ourselves and guard against inequalities of the temperature, "Othello's occupation" as related to the doctor would be gone.

This ideal condition can not be secured, but it may be approximated just in so far as hygienic laws are respected, while the individual progresses favorably along the lines of development, maintenance and repair. Let us recognize ourselves, then, as animated mechanisms, needing constant regulation; and to the extent of this regulation will we live healthy happy lives and progress to a delightful old age.

No person properly equipped in a proper state of health should want to die, nor should we have any other thought than that life is worth living, and that this is a beautiful world filled with very pleasant people.

We should all eat to live, certainly not live to eat, recognizing our bodies as a mechanical apparatus, an engine, as it were, with furnace attachments for the reception of fuel, said fuel to furnish force to run the mechanism. Let it be understood that this fuel should be properly selected and properly prepared for its proper consumption. Not only is this necessary, but in addition we must remember that there are no conditions yet developed in any force-giving mechanism where the fuel can be supplied in such perfect form as not to leave after its consumption a débris that is unavailable and which must be removed. The furnace must have removed from its interior the ashes of combustion which remain or we will have an interruption in its work. So with our bodies. The alimentary canal, the chief part of which is generally supposed to be the stomach, but which is not, is the receptacle for fuel in the form of food. The excretory organs, the chief ones of which are the kidneys and the skin, remove the unused materials and, in addition, the products which accumulate from the waste resulting from the various activities going on within the body.

CAUSE OF DISEASE IN MIDDLE LIFE.

It is becoming more and more evident every day that nearly all the diseases of middle and older life are interruptions in what is called metabolism, or tissue building, some break in the equilibrium of the process of nutrition. The food must be properly eaten, well digested and then assimilated, and the debris, together with those poisonous materials which accumulate in the system as the result of work upon the part of the various parts of the body, should be eliminated. Since the days of Garrod, the medical profession has appreciated to the fullest the fact that most of the diseases of adult and advanced life are gouty in their character. It is a popular idea that gout belongs only to the high liver and that it is generally manifested in one or both of the great toes, but it is exceptional for it to manifest itself in so localized a way. It is established that it is a universal condition, that it is dependent upon accumulation in the system of poisons (uric acid, etc.) that should be eliminated, and that said poisons may effect any one or all of the vital organs of the body. Particularly are the lining membranes of the heart and the blood vessels endangered, as they are similar in their construction to the lining membranes of the joints. Many so-called organic diseases, such as Bright's disease, cancer, diabetes and many of the distressing and dangerous diseases of the stomach are associated with the accumulation of uric acid in the system which is the disturbing factor in gout. At least these diseases are associated with the gouty condition, so that we are safe in saying that if we eat the proper food in the proper quantities and give due attention to its digestion and assimilation and have a thoughtful regard for the eliminative organs, the animated system of sewerage of the body, if you please, a ripe old age is sure to follow.

ESSENTIAL ELEMENTS OF FOOD.

I feel that I am in deep water in approaching the subject of diet, for voluminous books could be written upon this alone, but it is safe to present a few general principles. We must keep in mind the chemic constituents of the body and the fourteen elements going to make up this combination, viz., oxygen, carbon, hydrogen, nitrogen, calcium, phosphorus, sulphur, sodium, chlorin, fluorin, iron, potassium, magnesium and silicon.

There are seventeen combinations of the fourteen elements of food: Water, gelatin, fat, phosphate of lime, albumin, carbonate of lime, fibrin, fluorid of calcium, phosphate of soda, phosphate of potash, phosphate of magnesium, chlorid of sodium, sulphate of soda, carbonate of soda, sulphate of potash, peroxid of iron and silica. "The processes of life in the body have the following divisions: First, the governing portion, the brain; second, the executive portion, the muscular system; third, the fuel, which in a chemic sense, keeps up the supply of heat, which is the source of all activity and motion. Food must supply these three great divisions of the process of life in the proper proportion, or something will soon go wrong, though nature allows a wide margin. Of the fourteen elements needed in the body, and which must be supplied in the food taken to satisfy the three great demands, vitality, strength and heat, I shall classify under the general terms as follows (the words being used in their proper and not chemic sense): The phosphates, in which phosphorus predominates, supply vitality, or brain, nerves and bone; nitrates, in which nitrogen predominates, supply the muscles with strength; carbonates, in which carbon predominates, supplying heat and making fat."

The best brain foods, or phosphates, are lean meats, fish, cheese, crabs, wheat, barley, oatmeal, almond nuts, southern corn, beans, potatoes, figs and prunes. The best carbonates, or heat-producers, are fat meat, sugar, butter, rice, rye, chocolate, dates, buckwheat, northern corn, white flour. Excess in this branch is the cause of poor health, poor blood and bad skin. The best nitrogenous foods, or muscle makers, are vermicelli, eggs, cheese, meats (particularly beef), southern corn, salmon, beans and peas. Phosphatic food for persons of strong mentality and those who study much, can not be too strongly urged. The best food is the cheapest. It is well to remember that in hot weather we should avoid carbonates, or heat makers, such as fats, rich cereals, sweets, etc. A liberal fruit diet at such times is well.

Shakespeare truly says: "Dainty bits make rich the ribs, but bankrupt quite the wits." Fat paunches make lean pates. "How can one be expected to study or work well who eats a breakfast in warm weather, consisting of ham and eggs, white bread and buckwheat cakes. He complains of a tired feeling and biliousness and is dosed for malaria, when all he needs is a mild cathartic, change of diet and perhaps some pronounced exercise such as a half cord of wood to saw."

IMPORTANCE OF EXERCISE.

In this connection let me say a word in favor of exercise, judicious, temperate exercise. Proper elimination or removal of waste matters on the part of the individual absolutely demands muscular activity, but in securing this let us not misdirect our energies. The aggregated force which is lost in gymnasiums and other forms of exercise, together with bicycles, would move mountains and help build up the waste places of the earth if properly directed. The bicycle temperately used is a good thing for both sexes, but unfortunately it is so alluring as to be used to excess in the majority of cases. I am disposed to think the bicycle is a good deal like alcohol in its various forms, all right if used right, but under existing conditions neither the one nor the other is apt to be used right, particularly by the young.

The excessive use of coffee and tea are responsible for many nervous diseases, indeed far more than alcohol. The former can be used to enormous excess and the excess be within the limits of respectability, whereas the excessive use of alcohol soon disgraces the individual and thus many are under restraint.

Good teeth.—The well-to-do and those who are not forced to limit their supply of food are eating too much. Yes, it is true, that man is daily digging his grave with his teeth. If the stomach could talk it would call upon us to listen to a terrible tale of woe. How our sympathies would be aroused. Cultured and refined people (eventually the world at large will follow in their footsteps) have an appreciation of the dental profession and patronize it liberally and this is tending in the direction of longevity. The gateway into the nutritive system of the body is the mouth, and the teeth in their grinding capacity go to make up the keystone in the arch of digestion. The parent should have the child's teeth carefully guarded by the family dentist from early infancy. The world is living to eat rather than eating to live, and we all know that it is living too fast and that it is eating too fast. Every one conversant with the numerous stomach disturbances will testify that the first essential for good eating and good digestion is a good healthy supply of teeth. I presume that if the truth were known it would be found that the Bismarcks and the Gladstones and their progenitors have been possessed of good teeth.

Do not ignore the palate.—I do not believe that it is safe to ignore the palate. I think the tickling of the same helps digestion, gives a gentle comfort and pleasure which favors assimilation, and yet this is not at all incompatible with due consideration for the proper chemic make up of the food. Would to God that the strong-minded women of the world, those reaching out for higher education, those believing, and very properly, that woman has a right to the highest seat in the forum and sanctuary, and the highest hat in the parquette, and to the most elevated position in the community alongside of man in every relation of life—would to God that they would devote their minds, not less to Browning and other literary fads, but concentrate themselves more upon the problems related to nutrition, to the proper feeding of the world. A recent vagabond poet correctly expressed it when he said:

"Fair woman, could your soul but view the intimate relation
'Twixt food and fate, ther'd be a new and higher dispensation.
Could you but see for 'destiny' a synonym in dinners
And what the kitchen's alchemy could make of mortal sinners,
You'd leave odd fads and learn to bake a loaf and cook a 'tater,'
To roast a joint or broil a steak, than which no art is greater."

"What deeds of fame are left undone,
What thoughts are left unspoken,
What waiting laurels ne'er are won,
What grand resolves are broken,
Because of soggy bread and pies
And viands spoiled in broiling,
Of sickly tarts and greasy fries
And coffee left a-boiling!"

Let men rule the world as it is now planned, while woman by her sweetness governs man, but let a part of that sweetness tend in the direction of catering to the best interest of his stomach, and she will find that her governing power will be greatly enhanced. If the women of the world would devote themselves to the study of the chemistry of food, to the beauties and advantages of asepsis or absolute cleanliness in the kitchen and to the philosophy of digestion and nutrition, they would be much better equipped for being good mothers and helpful wives. I would gladly give to woman the ballot if she would be willing to confine herself in its use in the management of our public schools. Surely she could manage them better than they are managed in some sections today, and when the time comes that she has them under control, I trust that she will at once introduce into every school in the land a manual training department where all will be taught how to use their hands to good advantage in the direction of becoming bread winners and bread makers. Let every boy be taught the principles of some trade and every girl the elements of housewifery, such as cooking, sewing, etc. This training will the better fit them both for becoming homemakers.

A tranquil old age.—But we are drifting away from the needs of old age, and yet I am confident that these points and many others which might be presented for the good of the rising generation, would also be for the betterment of the aged. We should study constantly to evolve knowledge of that which will be conducive to a tranquil old age. The term old age is a relative one. It is said that a woman is as old as she looks and that a man is as old as he feels, but science is correct in the statement that every individual is as old as his arteries. In other words, the condition of the arteries, the vessels which carry the blood which goes to make up the circulation; their elasticity, their ability to dilate and contract in the proper way, is the expression of age or youthfulness. Let us strive to pursue the course of life most disposed to retard the appearance of old age. While this unquestionably involves good digestion and proper assimilation of food, in other words due regard to all that pertains to nutrition, to waste and repair, something more is needed. Young and old need to know that there are very few of us in this world, whether engaged in physical or intellectual labor, injuring ourselves by overwork. Neurasthenia or nervous exhaustion, so-called, is more frequently nerve poisoning, and indeed we may class those apparently diseased conditions of the nervous system, along with neuralgias and many others, under the head of gout, and these and nearly all the rest can be prevented by proper attention to diet.

Need of exercise and rest.—Advancing age needs to know the importance of proper exercise, that every muscle and part of the anatomy must be worked in order to maintain its functions. As the unused door hinge and lock become rusty and useless, so too with various parts of the animal mechanism. Proper exercise is essential, but we must have due regard for rest and rest at the proper time. As the individual passes along down the other side of the hill where the shadows lengthen he needs more sleep; he needs to know himself now if ever and feel within himself the peace of heaven and earth, a still and quiet conscience. This has to be accomplished by a good and worthy life on general principles. He with the silvery livery of advanced age, whatever his past life has been, is generally willing to be more correct, less frivolous, with a higher regard for morality and a greater contempt for the vices of civilization, and this is fortunate.

Fifty, the "Prime of Life."—As we advance in years let us be in line with Fleming in Longfellow's "Hyperion," when he says: "For my part I am happier as I grow older. When I compare my sensations and enjoyments now with what they were ten years ago, the comparison is vastly in favor of the present. Much of the fever and fretfulness of life is over. The world and I look each other more calmly in the face. My mind is more self-possessed. It has done me good to be somewhat parched by the heat and drenched by the rain of life."

A worker in any field, whose age is near either the shady or the sunny side of fifty, should consider himself in his prime, good for another half century of temperate judicious work. Mr. Henry King (now managing editor of the *St. Louis Globe Democrat*) of St. Louis, one of our best writers, has recently written: "However much men may distinguish themselves before they are 55, they sho [illegible] qualified for better work than any [illegible] ously done. Their triumphs do not convey the idea of completion so much as that of preparation. They have become well versed in the philosophy of success; they are masters of the situation by virtue of their experience; they are on friendly terms with fate because they have not failed to draw a profit from the things they have seen. The accumulation of years counts affirmatively and not negatively with respect to the ability of such men to promote the public interests and protect society against the errors of pretenders and ex-pretenders. They are not old men except in seniority and practical wisdom and in contrast with those who have yet to learn the beneficial lessons that only time and stress can impart. It is absurd to say that they lag superfluous when in fact they are at the zenith of their power. The fire does not burn as brightly in their case as it once did, to be sure, but the moderate glow is steady and well directed, and there is more to be expected from it than from the eager and unrestrained flame which is all promise with no assurance of performance."

Temperate living.—Immoderate drinking of whisky (*Brit. Med. Jour.*), like immoderate drinking of tea, or for that matter immoderate eating of bread, will shorten life; but what evidence is available on the subject seems to show that a strictly temperate use of alcohol tends to prolong life, for the excellent reason that it assists digestion, and thereby promotes health. The most trustworthy statistics on this subject are those of Sir Geo. Humphrey. Of forty-five cases of centenarians collected by him, only twelve were total abstainers while thirty were moderate drinkers. Of one hundred persons between 80 and 100 years of age, in Sir Geo. Humphrey's table, only a fraction over 12 per cent. were heavy drinkers. The abstainers would appear from these figures to have only a slight advantage over the the non-abstainers. The real secret of long life is well expressed by Sir Geo. Humphrey when he says: "The prime requisite is the faculty of age in the blood by inheritance. In other words, if you wish to live a hundred years you must, as Oliver Wendell Holmes said of another matter, begin by going back two or three hundred years and securing for yourself a sound and long-lived ancestry.

While heredity is of importance, bear in mind that the deficiencies of heredity can be made up by correct living. Given an individual with a poor inheritance, a fair physique and intelligent appreciation of the laws of health, who governs himself, and he is a safer risk for a life insurance company than one with an ideal heredity and equipment, careless and reckless.

Brain work conducive to longevity.—One of the brightest and best men in America today, a man who earns a salary of $50,000 per year as the manager of a great railway system, and who yet seems to have more leisure to make after-dinner speeches, etc., than any other man in America, Mr. Chauncey M. Depew, who recently celebrated his sixty-fifth birthday, affirms that he is now able to do more and better work with less fatigue than at any other time in his life. His career has been a busy one, with a constant drain upon his energies, but it has not yet made an old man of him. The record of multiplied years in his case does not carry with it the penalty of exhaustion and superannuation. It has been afternoon with him for twenty years, and still it is not sundown. He has trained himself to do a maximum of service with a minimum of effort; he knows how to concentrate his mind upon the essentials and to dismiss the non-essentials with a smile. Indeed, there can be no question that men who use their minds, in other words, brain workers, in consequence of the discipline through which they have passed, are better equipped for longevity than others. An enormous list could be given which would demonstrate the truth of this statement. It is interesting, however, to note that no one has outdone Michael Angelo in old age. Humboldt ceased at 85, but we find Angelo reaching further on and touching the verge of 90.

At 71 he drew the design for the rebuilding of St. Peter's and superintended that work until he was 89 years old, when he died. And during the first four years that he gave to the design, which has been a revelation of genius to all that have seen it, he painted his masterpiece "The Conversion of St. Paul." In the ten years preceding, he did "The Martyrdom of St. Paul" and the "Last Judgment." He died in harness at nearly 90, with the strange regret that he should have fallen so young. Titian lived to greater age than Angelo, almost reaching his one hundredth year. The thought of death never troubled Titian. "It is so far off." he said "there will be plenty of time to think of it by and by." He thought he was quite young at 80, and promised himself twenty more years of hard labor. At 78 he finished his "Martyrdom of St. Lorenzo," the last of that long list of great paintings that Titian executed. At 80 he set to work on the "Last Supper," but he had not gone far, about one year, when he saw that his ideal was escaping him. The old man turned from his work in despair, but afterward resumed it and was 87 years old when he finished that picture. It is called a masterpiece, but Titian himself did not think so. Stradivarius made his last violin in 1736, when he was 90 years old. His sight failed at 85, but he still made fiddles. At almost one hundred this man, who had never known rest, and who at the same time had never worked excessively, spent one year doing nothing and then died. It will be noticed that he held out two years longer than Michael Angelo. De Beriot is said to have owned the last violin made by Stradivarius, which he thought the finest instrument in the world.

It is interesting to know that C. A. Stephens, M.D., of the Boston University Medical School, is reported as saying he is convinced that the progress of brain science will enable mankind to successfully overcome decay and its climax, death. He further states his belief that death at 70 years or therabouts is due to the fact that generation after generation is born into the world expecting to die at that time and therefore die. He expresses the opinion that if children were brought up to believe they would live indefinitely, the life limit would gradually be extended in the course of several generations.

Keep the heart young.—As we grow old we need to know that we will remain young if we keep the heart young, and this we can do by mingling with the young. All who have seen Sara Bernhardt, at an age close to 60 years, have marveled at the youth that glowed in her face and permeated her lithe and willowy form. When asked for her secret, "I have my art" she replied, "I work, work, work. In work I take my greatest pleasure. It is a tonic; a delicious preventive of age. I sleep, and I never drink wine. I act. There you have it all."

This is the very concentration of wisdom; enthusiasm, work and sleep, these are the trinity making and keeping men and women always young and always useful, and let it be remembered that enthusiasm and joy in work is of most valuable import, and we can, if we will, cultivate enthusiasm for our work. Truly the worker is happier than the idler at all times, even though the latter be possessed of millions. M. Huret once asked Baron Alfonzas de Rothschild for his views of happiness; whether he thought that wealth brought happiness, and in answer the millionaire said: "That would be glorious. Happiness is something that people toil for." I suppose, he added reflectively, "some advantages do attach to money or people would not give themselves so much trouble, but believe me the truest source of happiness is work." It will be noted the world over that the world's greatest workers, who give attention in a reasonable way to the laws of health, are much more apt to live to an advanced age than the drones. People of advancing years who try to look young in the social world retain their youth by so doing. Let grandma wear bright ribbons and gaudy gowns if the colors become her, and grandpa be dudish as he pleases with flashy neckties and cheerful garb; both will be the younger for it and, besides, it is in harmony with nature. The trees take on their brightest colors as the winter of their life draws near. The older one becomes, the more they should avoid dark and somber hues, and this includes the capillary covering of the heads of both sexes. Gray hair is honorable, that which has been dyed is an abomination before the Lord.

Cultivate thankfulness, cheerfulness and love.—Cultivate thankfulness and cheerfulness. An ounce of good cheer is worth a ton of melancholy. "A merry heart doeth good like a medicine, but a broken spirit drieth the bones." Cultivate to the last the ability to love, realize to the fullest that the greatest thing in the world is love. Be like the curate of Olney, who said of himself, "he could live no longer than he could love." Without love there is no joy in life. Let us as we grow older realize the need not only of work, a proper physical and mental occupation, but of play, recreation and study. Let the work be as far as may be in the direction of helping others to help themselves. Nothing keeps one young like thinking of and having a sympathy for others. Canon Farrar was right when he said : "We often do more good by our sympathies than by our labors, and render to the world a more lasting service by absence of jealousy and recognition of merit than we could ever hope to accomplish by the straining efforts of personal ambition. In the cultivation of a sympathetic heart we do ourselves more good than those we serve. As we grow old let us cultivate a sympathy for the world at large, for its weaknesses, for the young, and the returns will come to us a hundred fold. The world ever gives us freely that which we give to it. As Shakespeare puts it, let us consider the capacities of those that are young and not measure the heat of their livers with the bitterness of our own galls.

No sweeter epitaph was ever written for an aged one on marble shaft than one noted, I think by Oliver Wendell Holmes, a tribute of an aged husband to his life companion, viz.: "She was so pleasant." Yes, let us, like the author of the first epistle to the Corinthians (which, by the way, is the sweetest love-letter ever written by mortal man or woman), determine to grow old gracefully along the lines of love. It will be remembered (says Drummond) that in the beginning love was not the strongest point of Paul, indeed his hand was stained with blood; but the observing student can detect a beautiful tenderness growing and ripening all through his character as he gets old, inspiring that same hand to write, "And now abideth faith, hope, love, these three; but the greatest of these is love." As we grow old let us not forget that "we shall pass through this world but once. Any good thing, therefore, that we can do, or any kindness that we can show to any human being, let us do it now. Let us not defer it or neglect it, for we shall not pass this way again."

Regard for youth.—Old age needs to appreciate the importance of consideration and respect for youth, that it is in the line of its duty and its own interest to treat the young gently, kindly, sympathetically, to advise them in such a manner as to invite their advice rather than to attempt to direct and conduct. I would say with Thackeray:

> "We suffer and we strive not less, not more, as men than boys,
> With grizzled beards at sixty-five as erst at twelve in corduroys."

Indeed, in the affairs of life extreme old age should be willing to assume a position of consulting engineer rather than that of director-general. As Max Nordau says, there are men born to rule, who refuse to bear another's yoke or to submit to another's control. They want their heads and their elbows free. They are only able to yield to the discipline of their own will and judgment, never to those of another. They submit because they choose or think best, never because they are compelled to do so. These individuals never meet with a barrier that they do not demolish or ride over. Life does not seem worth living to them unless they experience that satisfaction produced alone by the unchecked play of all their capabilities and inclinations. The consciousness that a large part of their horizon is obscured by some alien consciousness removed alike beyond their influence and observations, destroys their enjoyment of it; they look upon *ego* as a cramped and wretched *ego*, incapable of stretching and asserting itself; their very existence appears insupportable to them if they consider it impelled and guided by alien forces. Such individuals require room. In solitude they find it without effort or difficulty. If they are anchorites, if they are hermits or fakirs, Canadian trappers or pioneers of the backwoods, they can live out their lives without conflict with others. But if they are to remain in the society of man, there is but one place for them, that of leaders.

Such a one this century has had in the German Prince Bismarck, and there are others. It is difficult for such to adjust themselves to the changed conditions of advancing years. Unless they have a care, the latter years of their life will be very unhappy. All such need to bring their strong minds to the contemplation of ways and means of growing old gracefully, and not mar a magnificent record by the unpleasant shadows of their latter years. Such are apt as parents to always look upon their progeny as children and are never willing to give up controlling them.

Cultivate a religious or philosophic spirit.—Philosophy or religion should enable such to make their last days among the most attractive of their lives. Who will not say that the magnificent fight on Mt. McGregor by the grand "Old Commander" was greater than any with which he was connected from Fort Donelson to Appomatox? And a more glorious victory was never won by mortal man. The sweet gentleness and patient resignation with which he bore the suffering, the majestic courage that enabled him to write the book that drove the wolf from the door of the home that he loved so well; no grander event looms up on the records of history. A noble mind, soothed and comforted by faith, a consistent religious belief was his prompter. Religion, it is unquestionably that which is making the last days of England's "Grand Old Man," Gladstone, bright, cheery and helpful.

A sweet and noble faith it was that enabled one of St. Louis' ablest and best doctors, L. Charles Boislinière, to live a long and useful life and accept the sorrows, disappointments and agonies of prolonged illness in the latter months of his nearly four score years and ten, and receive his last summons in the same gentle graceful way that he would have received a message of love from the sweetheart and wife of his younger days and his ripened age. Yes, many a day will come and go before a brighter, better member of the medical guild will live as well-rounded and beautiful a life in our midst, and drift out as gracefully, calmly and beautifully into the great ocean of eternity as Dr. Louis Charles Boislinière, who recently went from among us. This good and heroic one, whose remains found a resting place 'neath the shadow of the cross on the silent slopes of Mt. Calvary, is in evidence in favor of a graceful old age being assured to the well-trained mind sustained by religious convictions.

Keep the mouth shut.—As a guard to health old age needs, and by the way, people of all ages as well need to know that it is necessary to keep the mouth shut, for it was not intended for breathing purposes, the nose being essential to this purpose and having the advantage that it warms the air and strains from it irritating matters injurious to the lungs. Remember, the mouth is exclusively needed as a port of entry for food and a port of exit for crystallized thought, the chief medium of communication between man and man. It is well for all to remember, though unfortunately, the sick and suffering and the aged, should especially remember that, save in rare exceptions, unkissed kisses are the best. Indeed, in this connection let me say that the kiss is only good for family use, and since we know that more than one hundred varieties of microbes have their home in the average undisinfected mouth, I insist that the aseptic kiss is the only permissible one anywhere.

The rights of old age.—Undoubtedly if old age pays due regard to those things classed under the head of needs and grows old in a smooth and easy way, accepting changed conditions in a proper manner, the rights to which they are entitled will be more willingly granted, but whether they do or not they are entitled to many rights which too often are denied them. Old age has a right to be guarded, protected, respected, to be treated with every possible consideration. Indeed, I feel that the second childhood demands even quite as much tenderness, patience and thoughtfulness as the first. Let us remember that in the equipment of the old the head yields before the backbone, that the judgment, the ability to reason well, soonest flutters in the battle of the cells that are tending deathward, and the emotional centers, together with a firm spinal column, are soon all that is left; in other words, the unyielding will, undirected by reason, soon assumes a very unpleasant form of stubbornness. But all this should be met cheerfully and patiently, because it will be but a little while until it is over and the memory of kindness and service of the past should inspire in the direction of reciprocity. Our aged ones have a right to claim our veneration, our love, and we should constantly give them the evidence of it.

> "Oh, friends, I pray tonight keep not your kisses
> For their dead, cold brow.
> The way is lonely, let them feel them now.
> Think gently of them, they are trouble worn,
> Their faltering feet are pierced with many a thorn.
> Forgive, oh, hearts estranged, forgive, they plead;
> When dreamless rest is theirs they will not need
> The tenderness for which they long tonight."

Respect for authority on the part of the young.—We need to preach a gospel to the young of America, calling for more respect for authority, a greater respect for age. The very air in our country is charged with democracy. The spirit of the Declaration of Independence has permeated every fiber of our population and we must have a care or sorrow will come. We must teach that reverence is not servility. Chancellor Hoyt very truly said thirty-three years ago, and it is more true today: "We do not in the intensity of our independence discriminate between reverence and its counterfeit presentment. The dread of appearing servile has led us to be irreverent alike to the aged, to station and to things sacred." Sacred history relates that in the entertainment given by Joseph to his brethren, they sat before him the first-born according to his birthright, and the youngest according to his youth. Herodotus tells us that the young men of his country and time yielded the road to age and rose from their seats before the hoary head. It is a noticeable fact that Demosthenes, the foremost man in the Athenian senate, was compelled to apologize, in his first philippic, for rising to speak before all the older members had delivered their sentiments. The liberty and national existence of Greece were at stake, every heart was glowing, every ear was erect to hear the burning words of the greatest orator in the world, and yet Attic patriotism was subsidiary to Attic politeness. Xenophon has recorded liberally the evidence in favor of the custom of the Greeks being uniformly deferential to the aged. The only exception to this rule being that old bachelors were not considered by the Greeks as entitled to the ordinary courtesies and amenities of social life, and to them, therefore, boys and girls alike might be as saucy as they pleased without fear of punishment. So it seems that even in the classic times the old bachelor was left to paddle his own canoe. But no intelligent man should remain a bachelor until he is old, unless he can furnish excellent reasons for doing so.

Cicero has recorded that respect which is paid to age forms an infallible criterion by which to determine the moral advancement of a people. We all recall the fact that the Greek and Latin races considered morals and manners as synonymous terms and even now the proper thought is that ill manners are not only vulgar but positively wicked. Young America will be happier as youth, adult or patriarch, if he is taught to know his place and to respect his elders. He must be trained in the direction of making proper genuflections and now and then to gracefully bend his back and droop his eyelids with respectful regard. He must also be taught to know that there is such a thing as rank in America as well as elsewhere, that while all men may have been created free and equal, they do not remain so, and their rank and station depends upon their achievements. It is with feelings of sadness that I see men and even boys sit in the presence of ladies standing, and I sometimes fear that our "new" woman is somewhat to blame for it. But we must cultivate and stimulate a different spirit, not only polite consideration for woman, in that no matter how low her place, she stands as a representative of sister, wife, daughter and mother; but due respect for place and power; due regard for worth and work, and a proper reverence for things sacred. I am disposed to believe that we Protestants have protested too much; that in stripping the church of the decorative features and various forms which we thought smacked too much of barbaric idolatry, we have gone too far. The bowing of the head in the presence of the Cross, even extremer forms of worshipful regard for things which are suggestive of the eternal, are better than irreverence.

The previous reference to the respect for age on the occasion of the feast given by Joseph to his brethren, brings to my mind the thought that we all could learn a lesson from the Jews in their home life, in their regard for old age. The dear old mother and grandmother of the Jewish home, and the patriarch with the bowed form and grizzled beard, has the seat of honor on all occasions, and no corner of the house is too bright, cheerful, warm and cozy for them.

Are we not justified in believing that the most attractive feature of the Jewish people, their home life, their disposition to make the entire earth, including the Gentiles, contribute to the joy and comfort of their home, has been largely brought about by the reverential regard for old age which has been a part of their history through all the centuries of the past?

Reciprocity.—All of us should have a prompting in the direction of recognizing the rights of the aged, for the time will come when we will wish to have such rights accorded to ourselves; so we should be somewhat actuated by the same sentiment as the individual referred to by Holmes who is recorded as having written his own epitaph, as follows:

"Here lie I, Martin Elginbrodde,
Have mercy on my soul, Lord God,
As I would do were I Lord God,
And ye were Martin Elginbrodde."

To the young then we would say, be ever thoughtful of the feelings and rights of your elders, for whether you expect it or not, you are apt to receive in return, before the end of life, that which you give to others. "Now gird thee well, my youth of twenty year, against the marching morrows that fill the world with fear."

Politeness.—The parent can not begin too young to inculcate the truest politeness, which, after all, is but consideration for the rights of others. A reverential regard for gray hairs can be made so completely a part of the education of the home by precept and example as to make it come easy as the years pass. I think it is a good plan to take the child from time to time, to the house of the aged and impress him that it will be but a little while until his own parents are quite as old and helpless as those about him. His sympathies can be drawn upon easily, and if proper effort is made it will not be long until even "unlovely old age" will receive due consideration. In the daily walks of life the child should be taught, if the means of the parent at all permit, that no beggar with gray hair should ever be permitted to escape without receiving something. Indeed, I am disposed to think that a refusal to relieve any form of need should never be expressed in a child's presence, unless a complete explanation be given for the refusal. Never failing to make a proper effort to stimulate and develop a proper ambition in the child he should soon be taught that "at best we are all mendicants waiting along the roadside in the sun, tatters of yesterday and shreds of tomorrow clothe us everyone."

Close of life means rest.—A ripe old age gracefully and gently approaches the final hour with a weary feeling, ready and willing to take rest the moment that it comes, and in response to the query, "What is death"? it can realize that it is "a rest from vibrations of sensations and swayings of desire, a stop from the ramblings of thought, a release from the drudgery about our body." It can say with the old tent-maker of Arabia, "Why, if the soul can fling the dust aside and naked in the air of Heaven ride, were it not a shame for him in this clay carcass cripple to abide?" May that soul not believe with the same old pagan tent-maker that,

"We are no other than a row
Of magic shadow-shapes that come and go
Round with this sun-illumined lantern held
In midnight by the master of the show.
And that inverted bowl they call the sky,
Whereunder crawling, cooped we live and die,
Lift not your hands to it for help—for it
As impotently rolls as you and I."

But rather have an abiding faith that all is well. But, whether you have that faith which is so satisfying to those who possess it or not, you at least can be satisfied as the pagan philosopher, feeling safe in that he who ordered the first scene in your life, now gives the sign for shutting up the last. You for one, therefore, can retire well satisfied, for he by whom you are dismissed is satisfied also. But after all,

"As a fond mother when the day is o'er,
Leads by the hand her little child to bed,
Half smiling, half reluctant to be led,
And leaves his broken playthings on the floor,
Still gazing at them through the open door,
Not wholly reassured and comforted
By promises of others in their stead,
Which, though more splendid, may not please him more,
So nature deals with us, and takes away
Our playthings one by one, and by the hand
Leads us to rest so gently, that we go
Scarce knowing if we wish to go or stay,
Being too full of sleep to understand
How far the unknown transcends that we know."

May each and everyone of you live to a ripe old age in harmony with the last words of the great Victor Hugo, "Winter is on my head and eternal spring is in my heart. The nearer I approach the end, the plainer I hear around me the immortal symphonies of the worlds which invite me. For half a century I have been writing my thoughts in prose, verse, history, philosophy, drama, romance, tradition, satire, ode, song; I have tried all. But I feel I have not said the thousandth part of what is in me. My work is only a beginning. The thirst for infinity proves infinity."

May you have troops of friends, prattling children clinging lovingly about your knees and necks, and when the final summons comes and your last good-byes are said, may you wander over upon the other side of the beautiful hills of eternity, happy in the thought that you will greet many more loved ones there than you leave behind.

Let us have a Department of Public Health!

ORIGINAL ARTICLES.

NEUROTIC ATROPHY OF BONE.

BY ARTHUR E. PRICE, M.D.
AWARDED THE J. W. FREER MEDAL, RUSH MEDICAL COLLEGE, CHICAGO, 1897.

The study of neurotic atrophy of bone as a pathologic research, may be outlined in general in the same manner as ordinary atrophy of these structures; not necessarily depending on the causes of the latter, but resembling each other greatly in the characteristic state of degeneration. The change is a structural one in which certain portions of cells that properly should combine with oxygen are thus rendered soluble and remain; a fatty degeneration ensuing.

Thomas Curling of London, was the first to differentiate between concentric and eccentric atrophy of bone, by experiments with electricity, on degenerated nerves, and by cutting off the blood supply to bones. He demonstrated that the nutrition and also the vital powers of bone, being suspended, a process of resorption of the harder or more component parts occurred, and the compact structure changed into one closely resembling cancellous tissue. The gradual softening and loss of weight and size, he termed concentric atrophy, but closely allied however to eccentric atrophy, in which the medullary and Haversian canals enlarge and become porous (osteoporosis) with a corresponding diminution of weight and size. The atrophy progressing steadily, leads to diminished activity and cessation of function.

It is proposed in this article to classify the various changes which take place in connection with neurotic atrophy of bone, from an etiologic standpoint. 1. Tropho-neurotic changes occurring in paralysis of muscles in connection with bone, and a lack of exercise, resulting in atrophy. 2. Neuropathic conditions of the central nervous system and its tributaries.

In order not to deviate from the subject allotted, and to limit myself to the classification already made, it will be essential to keep in close relation to the medium along which the neurotic atrophy of bone is brought about, viz., the cerebrospinal and sympathetic nervous system.

1. *Tropho-neurotic changes.*—Bone may atrophy from mere want of exercise, due to certain nervous diseases which cause paralysis of the muscles; such changes occurring in progressive muscular atrophy, anterior poliomyelitis, locomotor ataxia, etc., illustrating the characteristic manner by which bone atrophy is accomplished.

Pathologic changes occurring are evidenced by the large ganglionic cells of the anterior cornu of the spinal cord becoming pigmented and atrophied; also extension of lesions along the anterior or motor nerve fibers, resembling the degeneration following nerve section in the lower animals and resulting in the breaking up of the medullary sheath, disappearance of the axis cylinders and proliferation of the nuclei in the walls of the sheath of Schwann.

The paralyzed muscles undergo fatty degeneration of the muscular fibers, so that their functions are abolished and the result is atrophy of bone and other tissues, resulting in deformity of limb and more or less loss of function. Lack of use, therefore, is thus followed by an arrest of development, and also by resorption of the more essential elements of bone.

The increase of the earthy salts, elimination of the cellular elements and diminution of vascularization tend to make the bones brittle (fragilitas ossium), from which condition, if far advanced, fractures occur from most trivial causes, such as multiple fractures, so generally regarded as conspicuous clinical features. Landerer reports a case of locomotor ataxia in a man 23 years old, who had suffered eight fractures, and in each instance the fracture was the result of an insignificant injury.

Again, heredity and insanity seem to be etiologic factors in fragilitas ossium. Pauli gives an instance of the former in which for three generations certain individuals of a family had suffered from extraordinary fragility of bones.

Jarvis S. Wight of Brooklyn, gives an interesting account of a case of fragilitas ossium with multiple fractures and vicious union and deformity corrected by osteotomy. Boy, 18 years old, fell and broke his right femur near the middle and came to Long Island Hospital, Oct. 28, 1890. On examination the bones of the thigh were found to be very much deformed and near the lower end bent considerably backward, the toes of both feet pointing directly downward. The history as given by the father developed the fact that his son had always had poor health and had been subject to fits and convulsions, and that this was, in his estimation, the cause of his crooked bones. The boy had already sustained several fractures of the long bones before entering the hospital. It is worthy of mention that he was an inveterate smoker and on ceasing this he appeared to improve rapidly for several months, without sustaining any more fractures. He however resumed the habit and rapidly grew worse and soon received two more spontaneous fractures; one near the middle of the femur, the other, of the radius. Shortly after this he died of intercurrent pulmonary disease.

Investigations show that in some instances bony union occurs in a shorter time than under ordinary circumstances, while in others the nutrition is so impaired that the callous formation is imperfect or entirely wanting. The usual treatment for fractures, to obtain bony consolidation with the limb in a useful position, should be observed in fragilitas ossium. Long confinement in bed should be avoided, by use of plastic circular splints, which will enable the patient to go out and enjoy the outdoor air and exercise within two or three days after the injury. Appropriate diet and good hygienic and sanitary surroundings should be recommended, and the internal use of potassium iodid in cases of defective callous formation.

Buzzard of London, presents three cases of locomotor ataxia, illustrating the resorption and friability in atrophy of bone:

Case 1.—A man in whom the hip joint was completely disorganized, the neck and head of the femur disappearing within a limit of three months.

Case 2.—Woman presenting typical clinical features of tabes dorsalis. While walking slowly along in the ward of a hospital the femur was fractured near its neck.

Case 3.—Woman; dislocation of left leg outward and backward on the femur. The bones could be brought into apposition, but the patient before putting on a leather casing, had to bandage them together. "It seemed as if the condyles had been beveled off and the end of the femur turned into a rounded and smooth stump."

G. T. Morton of Philadelphia describes a case of acute anterior poliomyelitis with atrophy of the bones of the lower extremity in a boy 4 years old. The child was born with club-foot. On examination he was found to have pure valgus of the right foot and the plantar arch also missing, giving rise to pes planus or flat foot. The right calf measured seven and one-half inches, the left eight inches and the right leg three eighth of an inch shorter than its fellow.

The following case occurred in Prof. Nicholas Senn's clinic March 16, 1897:

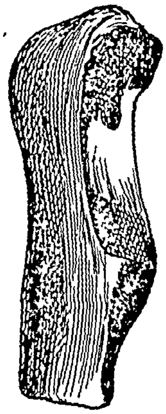

Fig. 1.

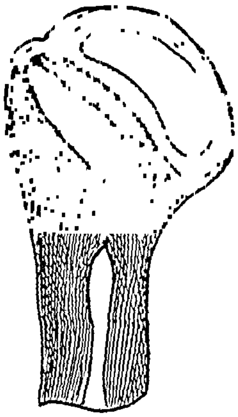

Fig 2.

Fig. 1.—Head of humerus from a case of acute ant poliomyelitis. Fig. 2—Healthy humerus for comparison.

Girl, 6 years of age, in which a probable diagnosis was made of acute anterior poliomyelitis. On examination the left leg was found to be an inch shorter than the right and evidence of displacement of an inch upward of the trochanter, by applying the Roser Nélaton line. The child was placed under an anesthetic and more careful examination of the parts revealed an atrophy of the acetabulum, with difficult coaptation of the head of the femur. The dislocation was reduced and the femur retained in position by plaster of-paris dressing. In conclusion; he stated that serious mistakes have been made by competent surgeons in operating for chronic joint affection by resection or amputation, mistaking the atrophy for an extension of the disease from the joint to the bones, removing consequently too much tissue, often necessitating an amputation for an intended arthrectomy or resection.

Charcot presented several casts to the Pathological Society of London, illustrating the friability and readiness to spontaneous fracture of bones in locomotor ataxia. Cast 1 showed the wearing away of the upper part of the femur, associated with an ununited fracture of the neck of that bone. Cast 2 showed extreme shortening of a femur after a fracture. Cast 3 showed left humerus to be dislocated beneath the clavicle, and head of bone apparently unaltered. The opposite humerus was dislocated on to the dorsum of the scapula and the head of the bone partly absorbed; also dislocation of the right knee joint (the tibia and fibula being twisted outward and displaced upward behind the femur), the lower end of the latter bone being partially absorbed.

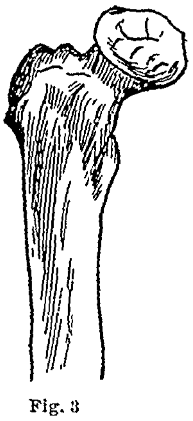

Fig. 3

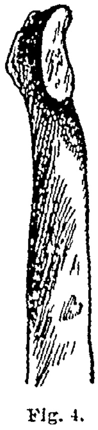

Fig. 4.

Fig. 3.—Normal femur. Fig. 4—Atrophied femur in a case of locomotor ataxia.

Charcot found in his researches in this direction, that the exact pathologic cause of these lesions was difficult to ascertain, for the reason that in some cases the ganglionic cells in the anterior cornu of the spinal cord were found atrophied on postmortem examination, while in others there was no associated muscular atrophy and the cells were found in a healthy state.

Friedreich, however, draws different conclusions, and adheres to the myopathic theory for progressive muscular atrophy, in which he asserts that there is an intramuscular inflammatory process, beginning with hyperplasia of the interstitial connective tissue, terminating in atrophy and fatty degeneration of the muscular elements. This chronic myositis he believes is capable of producing secondary disorders of the nervous system, by extension of the lesion to the intramuscular nerves and by a neuritis extending along the nerve trunks to the spinal cord.

Cruveilhier, Tardieu and others have demonstrated that the cells of the anterior cornu are primarily involved, as noted clinically by pain in the dorsal region, increase of reflexes, spasm of muscles, and peculiar reaction of muscles and nerves to the galvanic current. These symptoms coming on insidiously and later completely disappearing when the trophic disturbances appear in the form of atrophy of bones and joints.

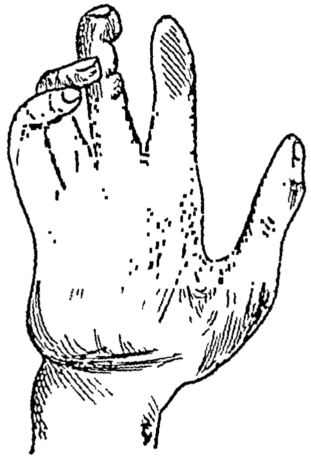

Fig. 5.—"Main en griffe"—injury to ulnar nerve (Duchenne.)

INJURIES TO NERVE TISSUE IN GENERAL.

The nerve trunks are exposed to various kinds of traumata, such as section, tearing, crushing, violent concussion, luxation, persistent compression, cauterization and suppuration, the immediate effect of which is an interference with the conducting power of greater or less extent and duration, according to the kind of injury sustained. With a continuation of loss of function paralysis of the part with wasting and atrophy ensues. In this manner it will be seen how easily a neurotic atrophy of bone could develop after gunshot and other wounds.

Schiff, in his experiments on section of nerves in the lower animals, found that the diameter of bones diminished considerably, the apophyses rounded, the medullary canal enlarged and the amount of calcareous matter greatly diminished.

Some of the worst cases of neurotic atrophy of bone may occur in connection with the upper cords of the brachial plexus, one or all of them being crushed by falls upon the shoulder, often leaving permanent paralysis of the corresponding bone.

Contractures and paralysis of muscles constitute the most rebellious motor disorders of traumatic origin. The contractures are due to a tonic spasm of the antagonists, caused by a paralysis of certain muscles from nerve lesions, crutch paralysis for example. The stiffness of the joints which occurs after fractures or other accidents, is due to forced immobility of the limb in an immovable apparatus, and in such cases we may prevent the bad effects (leading to an atrophy in course of time) by passive movements performed frequently and carefully. Paralytic contractures of the knee, the hip, and especially of the hand, where they may follow injuries of the ulnar, median and musculo-spiral nerves, are comparatively common.

Duchenne collected 100 cases in which the musculo-spiral nerve had undergone degeneration from septic and traumatic causes, and in every case all the parts supplied by this nerve became paralyzed, resulting in marked atrophy of bones of the hand and forearm.

Injuries to the spinal cord, such as fractures and dislocations, produced mainly by forced flexion (the head and neck being bent forward on the chest, or the thorax upon the pelvis), and severe traumatism to the brain are sometimes followed by a neurotic atrophy of bone in accordance with the motor area involved.

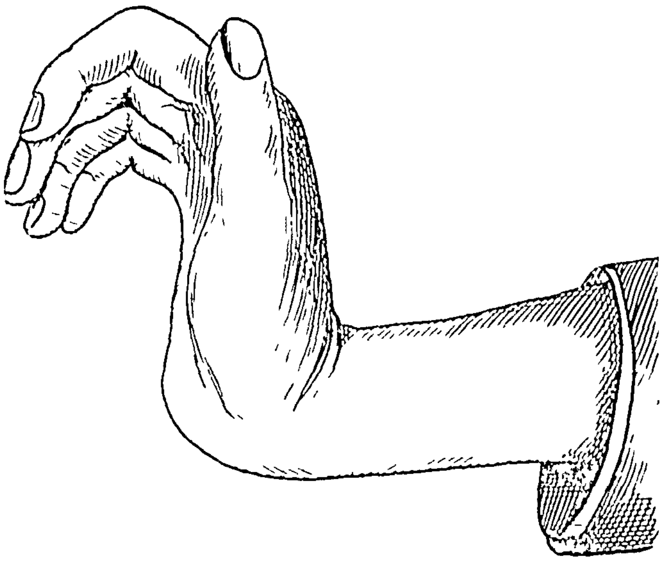

Fig. 6 —Position of hand in pachymeningitis cervicalis, affecting lower part of cervical enlargement

If the faradic excitability of the muscles persist the injury is in all probability slight, but if the faradic excitability disappears and remains absent for over a year the chance of recovery is small, and ensuing paralysis begins followed by atrophy of bone. The prognosis should be guarded, and means taken to preserve the nutrition of the part, viz, warmth, friction, massage, stimulating liniments and galvanism.

2. *Neuropathic conditions* brought about by action of pathologic changes, such as tumors of the cord, spinal hemorrhage, chronic inflammation of the cord, external and internal pachymeningitis, multiple cerebro-spinal sclerosis, infantile spinal paralysis, tubercular meningitis, syringomyelia, syphilitic gummata, progressive bulbar paralysis, *cerebral palsies*, *insanity*, etc., are all liable to eventuate in a neurotic atrophy of bone. The resorption of the essential elements of bone with shriveling, bending and brittleness, also occur under this class.

Paralytic contractures in certain cases followed by marked deformities, are exemplified in infantile spinal paralysis, the latter disease coming on without prodromata and with fever (104 to 105 degrees F.) followed by stupor and convulsion. Paralysis develops rapidly during the fever, but soon diminishes, leaving a permanent palsy, generally monoplegic and confined to one limb. Within two weeks faradic excitability is lost, followed by contracture of certain muscles and steadily progressing atrophy of bone. Characteristic contortions observed for the most part in the foot are pes equinus paralyticus and pes calcaneus paralyticus.

In the region of the spinal column paralytic contractures often take the form of lateral curvatures (paralytic scoliosis), or by flexion and extension contractures (paralytic kyphosis and lordosis). No doubt pressure upon the paralyzed part, by the weight of the body during standing and walking, aids somewhat in producing these deformities.

In syringomyelia the disease is for the most part localized in the cervical portion of the cord, followed by atrophy of bone of the upper extremities. In locomotor ataxia the atrophy is generally limited to the lower extremities. Traumatisms often play a predisposing part in connection with the neuropathic changes. Analgesia is always pronounced and large joints have been resected without the use of anesthetics. This analgesia is moreover the chief factor in furthering the development of disturbances of nutrition which is present in bones and joints.

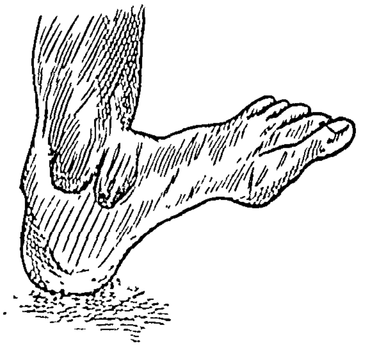

Fig. 7.

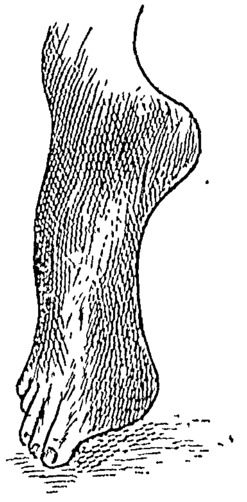

Fig. 8.

Contortions in infantile spinal paralysis. Fig. 7.—Pes calcaneus paralyticus. Fig. 8 —Pes equinus paralyticus.

The deficient nutrition is an impairment of the normal supply of blood, whereby the functions of the nerves are deranged. Aside from the physical and mechanical irritants (which are not a continuous process), the organized irritants, viz., anthrax, malignant pustule, glanders, and the more general diseases such as syphilis, tuberculosis, leprosy, typhoid fever, anemia and the like, are some of the prime disturbances in deficient nutrition. They permeate the system, spread wider and wider, invading the tissues farther and farther, and by so doing lowering the vitality of important nerve trunks and branches, until their energy is spent, or meeting with some part sufficiently nourished to resist.

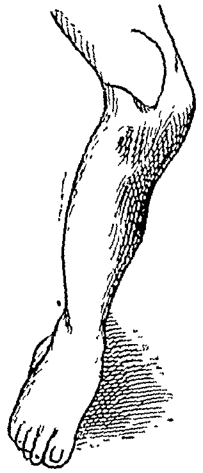
Virchow reports a case of progressive muscular paralysis and atrophy of bone after typhoid fever, ensuing without any evident nervous affection. He thought that it was in this quarter that pathologic anatomy might usefully direct its energies.

Dr. Vandyke Carter states that syphilitic lesions somewhat resemble those of leprosy, especially in regard to results. He cites a case of syphilitic thickening of the ulnar nerve near the condyle of the humerus, producing a paralysis of the interossei muscles, and later on atrophy of the corresponding bones.

In the new museum joining the École Pratique at Paris is a skeleton in which most of the bones of the body are anchylosed, resulting from a syphilitic gumma of the brain. Marked atrophy of the bones of the lower extremity is revealed, the femur being scarcely larger than an ordinary radius.

This vascular neurosis seems therefore to be an important etiologic factor in the neurotic atrophy of bone, and whether acting independently or conjointly with the trophoneurotic and neuropathic conditions, atrophic degeneration becomes the ultimate termination.

The treatment of neurotic atrophy of bone should be local and general. Of the former, fixation and orthopedic appliances are often followed by improvement. Firm anchylosis in a good position is preferable to a loose joint which is rapidly ground to pieces by friction, and arthrodesis performed in the early stages results in marked benefit. Should extensive destruction or suppuration occur, the question of arthrotomy, resection or amputation would arise.



F g. 9.

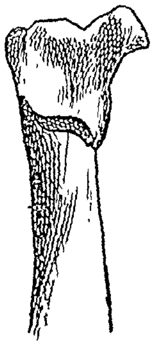


Fig. 10.

From a case of syphilis. Fig. 9.—Anchylosed limb. Fig. 10.—Atrophy of femur.

The general treatment should comprise those means best adapted to the special cause. Good hygienic surroundings, nutritious diet, with plenty of outdoor air and sunshine. In cases of strumous diathesis, cod liver oil and general tonics, such as Fowler's solution of arsenic and the syrup of iodid of iron, for anemic and enfeebled patients. When dependent on syphilis, daily inunctions of mercury and the use of iodid of potassium. Stimulating liniments, massage and electricity, are all excellent for the paralyzed muscles; weak galvanic currents may be applied to the spine for five minutes at a time every other day, and if the paralyzed muscles should respond, the interrupted galvanic current may be used.

Summary.—It has been the aim in this article to present the various forms of bone atrophy which occur in connection with nervous disorders, and to eliminate all other atrophies not depending on the causes of the latter. It would seem almost impossible, were it not for the general conclusions deduced (clinical and anatomo-pathologic) which have been presented, to differentiate from ordinary atrophy of bone. The gradual diminution, loss of weight, deformities, fragility, etc., are all characteristic features. Under these circumstances a positive diagnosis of neurotic atrophy of bone would be difficult, were it not for the otherwise *chronic course*, and *abolishment of pain*, *reflexes* and *electric excitability*, which are as a rule present to a greater or less extent in ordinary atrophy of bone.

Our knowledge, at present, in regard to the exact pathology of bone atrophy from nervous causes, is too meager to warrant any positive conclusion. Whether the degenerated and nutritive changes affect primarily the muscles, the peripheral nerves or the motor cells in the anterior horn of the spinal cord, is as yet undecided. There seems to be a consensus of opinion by some excellent authorities, as previously quoted, that the spinal cord is primarily involved.

It is also a question whether the spinal diseases such as syringomyelia and locomotor ataxia should be regarded as the direct causes of neurotic atrophy of bone, or only as predisposing. Charcot has lately adopted the view that certain localized processes of disease in the diaphyses and epiphyses, in conjunction with the spinal troubles are the sole factors in producing the bone atrophy.

It must be admitted, however, there is need of some more definite and positive theory, which, if substantiated by chemic and microscopic research, would shed light upon much that is obscure in the relations of the different affections included under the head of progressive muscular and bone atrophy.

TREATMENT OF COLLES' FRACTURE.

Presented to the Section on Surgery and Anatomy, at the Forty-eighth Annual Meeting of the American Medical Association, at Philadelphia, Pa., June 1-4, 1897.

BY EDWARD A. TRACY, M.D.
BOSTON, MASS.
FELLOW OF THE MASSACHUSETTS MEDICAL SOCIETY.

In 1814, Colles of Dublin published his observations on the fracture which today deservedly bears his name. Previous to that time this injury practically masqueraded under the description of backward dislocation of the wrist or forward dislocation of the lower end of the radius (!), for such dislocations were considered common by the masters from Hippocrates down. The nearness of the fracture to the wrist joint, the peculiarity of its anatomic surroundings, the absence of the characteristic sign of fracture unless specially sought for, and finally the teaching of the masters, all served to hinder the recognition of the actual occurrence in this injury, fracture. Therefore, to Colles will ever be due our appreciation and gratitude for the correct diagnosis of this injury, for correct treatment in surgery is depe[illegible] right diagnosis to even a greater degr[illegible]cine.

In this paper the writer will quote the views of eminent surgeons who have written on the treatment of Colles' fracture. It will be seen there has been a considerable change from the earlier days of over treatment to that in vogue at present, when the real nature of the injuries is better known. Sir Astley Cooper, after describing a method of dressing now obsolete, writes: "The arm should be placed in a sling. This position is to be preserved for three weeks in young persons and for four or five in the aged before passive motion be attempted. The recovery in these cases is slow, and six months will sometimes elapse before the motion of the fingers is completely restored."

John H. Packard ("Notes on Fracture of the Upper Extremity," p. 57) writes of a modification of Bond's splint, to which in some cases was added a dorsal splint, each with an elaborate padding of compresses. He says: "Very great care should always be taken to make these compresses of exactly the right thickness, and to lay them over the precise spots at which their effect is needed. An evenly applied bandage, making just the requisite degree of pressure, is necessary to the maintenance of the splint and compresses in their place. And I think that if, as a rule, the apparatus now described were kept on for at least six weeks we should have fewer cases of deformity after those fractures than at present. Often, indeed, I believe it might be retained with a gradual lessening of the size of the compresses for a much longer time, to the great advantage of the patient.

Swinburne ("Treatment of Fracture of Long Bones by Simple Extension," p. 43) employed a straight splint over the back of the forearm and hand, with a pad over the carpus and another near the elbow. The splint was attached to the hand and forearm by adhesive plaster, in a fashion that Swinburne believed produced extension of the parts involved. The writer is dubious of the extension produced by such means, but believes that Swinburne got the fragment into good position by manipulation, and that his simple splint and dressing kept it there. There was no interference with the fingers, and the dressings were discarded sometimes as early as the fifteenth day, generally from twenty-one to twenty-five days. Swinburne reported excellent results.

Bryant ("Manual for the Practice of Surgery," Philadelphia, 1885, p. 992) writes: "(The surgeon) ought to guard against stiff joints in the treatment of those injuries by employing passive movements earlier in the progress of the cases than he has been wont to do."

"After this form of fracture the wrist joint rarely recovers its normal movement, some deformity permanently remaining, and of this the patient ought to be warned" (p. 880).

Moullin ("Surgery," Philadelphia, 1895, p. 413) writes: "It is always necessary to warn patients that Colles' fracture is liable to be followed by stiffness affecting both the fingers and the wrist, especially if there is any tendency to gout or to rheumatism. It is due in many cases to strain and adhesion of the flexor tendons, but it is made worse by rigid confinement. So far as the fingers are concerned it can be generally avoided. Passive motion must be commenced and thoroughly carried out from the first day. With the wrist it is more difficult, but on several occasions I have begun gentle manipulations on the fourth or fifth day with excellent results."

Walsham ("Practical Surgery," p. 427) writes: "Practice passive movement from the third day, as in this form of fracture the tendons, where they cross the back of the radius, the seat of the fracture, are apt to become adherent to their grooves. Remove the splints in about four weeks, and employ shampooing, friction with stimulating liniments, etc., till any stiffness of the joint or fingers has disappeared."

McClelland ("Civil Malpractice," New York, 1877, p. 8) writes: "Notwithstanding the exhibition of the utmost care in the treatment of fractures in the lower third of the forearm, there is always more or less stiffening of the wrist and fingers, a result due, almost, if not entirely, to fibrinous exudations into and around the sheaths of the tendons, and to the adhesions which necessarily follow this fibrinous exudation when the parts are kept at rest for a long time."

Professor Agnew (*Clinic*, Oct. 25, 1871) said: "Difficulty of motion in the neighborhood of joints was a common sequel of this fracture, and, even under the most careful treatment, was found to exist in a majority of cases. He thought it due, not so much to injury of the joint itself as to adhesions of the tendons over the seat of fracture, by which their play was restricted."

It can thus be seen that, since the recognition by Colles of the real nature of this injury, there has been a marked tendency till within recent years to overtreat it with more or less baneful results. Sir Astley Cooper advised that four or five weeks be let elapse before passive motion, in the aged, be attempted. He remarked that recovery is slow, it sometimes being six months before the finger motions were restored. Agnew, Bryant, Moullin, Walsbe and McClelland all recognize that the stiffness of the wrist and fingers is due to fibrinous exudations around the tendon sheaths about the seat of the fracture. Bryant states that passive movements ought to be employed by the surgeon at an earlier period than has been wont; but that time he does not specify.

Moullin advises passive motions of the fingers from the first day, stating that this generally prevents stiffness of them. With the wrist, he states, it is generally more difficult (to prevent stiffness), "but on several occasions I have begun gentle manipulations on the fourth or fifth day with an excellent result." The writer believes that Moullin's very definite instruction in regard to passive movements of the fingers to be begun at once, and of the wrist joint on the fourth or fifth day, is good practice and that it ought to become general. All surgeons probably will agree with Roberts ("Fracture of the Radius," Philadelphia. 1897) that "the displacement (in Colles' fracture) is the result, not of muscular action but of the vulnerating force," and further, that "the muscular surroundings have little to do with the causation or continuance of the distortion." For this reason the fracture, if reduced, has no tendency to again separate. It would seem, therefore, that all that is needful after reduction of the fracture is some simple appliance that will protect the parts from accident during reunition, and that will not interfere with passive motion of the fingers from the first day. Swinburne's practice of many years ago, referred to above, was good, though his explanation of it, by the principle of extension applied to the parts, faulty. The writer in several cases, after reduction, has molded a piece of wood-fiber splint material over the dorsum of the forearm and hand in a semiprone position, the hand in line with the forearm. This, bandaged over the parts, he finds sufficient protection for them. It does not interfere with passive motion of the fingers, and is readily removed and reapplied to permit of passive motion of the wrist joint. It is molded directly over the skin, and requires no padding or compress. In these cases he has carefully caused passive motion of the wrist joint from the fifth day, and discarded the splint on an average of about twenty-one days.

The writer believes that the treatment of Colles' fracture could thus be formulated: 1, Reduction, not always easy; 2, protection by a simple retentive appliance while correct reunition of the bone takes place; 3, passive motion of the fingers from the first day; of the wrist, carefully, from the fifth day.

99 Broadway.

THE PASSING OF PLASTER.

Presented to the Section on Surgery and Anatomy, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY EDWARD A. TRACY, M.D.
BOSTON, MASS.
FELLOW OF THE MASSACHUSETTS MEDICAL SOCIETY.

At the Atlanta meeting of the ASSOCIATION, in a discussion before this Section, Prof. Thomas H. Manley of New York made the statement that "plaster-of-paris, as a routine treatment for fractures, should be discarded." The advanced ground taken by that able surgeon is certainly welcomed by the writer, who believes that plaster-of-paris, as a routine means of surgical fixation is doomed, and that its wane will be rapid because of its inherent defects and of the advantages possessed by its rival, wood-fiber splinting.

It will hardly be gainsaid that at present, particularly in the hospitals, plaster-of-paris holds sway as the routine treatment for most fracture cases. Routine, unless perfection has been reached, is baneful to progress in all fields of human endeavor. It can be so in surgery. Happily, however, in this field of activity, there are willing minds and hands to welcome whatever tends toward improvement in their art, and hence the power of routine is weakened; it can not strangle a new method without a trial by honest observers. It may seem an unimportant point whether plaster-of-paris or something better be used in cases requiring surgical fixation, but fractures are frequent and we shall always have them with us; any amelioration in their treatment or results deserves the attention of the profession.

In this brief article the writer proposes to state facts relative to the use of plaster-of-paris as a means of fixation, and of wood-fiber splinting used for the same purpose. A comparison of these facts will render obvious his reasons for believing that plaster, at no distant time, will be relegated to its proper place, a means of fixation to be employed only when more efficient materials can not be had.

1. *Facts of plaster-of-paris treatment of fractures.*—*a.* Plaster-of-paris is dangerous and sometimes deadly to the encased limb. F. H. Hamilton's testimony on that point is sufficient; many living surgeons can verify it.

b. It does not, as generally supposed, *immobilize the enclosed parts.* A moment's consideration makes one clearly understand how futile it is to expect immobilization of limbs swathed in soft and compressible cotton by a rigid bandage outside the cotton. Supposing the fixation to be efficient at first, it is soon destroyed by subsidence of swelling and, later, by tissue atrophy that always takes place in an idle limb.

c. It is destructive of the joint functions of injured joints, by preventing the timely application of passive motion to them. The timely application of passive motion to injured joints is an important indication in fracture treatment.

d. Plaster dressing prevents the surgeon's ready inspection of the parts treated, a condition not tolerated in an ordinary wound, and which, for as grave reasons, should not be tolerated in fracture cases.

Addenda—Dangers of plaster.—The dangers of plaster dressings can not be emphasized too much. Limbs have been lost by its use. The loss of a limb from any cause is fearful; from such a cause, horrible and indefensible. It could not occur if the treatment of such cases were to apply accurately molded splints retained by bandages, which should be removed daily as a matter of routine, until every iota of danger from pressure be gone. Such removal of bandages is easily and speedily accomplished, and allows the surgeon to *know* the condition of the parts he is treating—an impossibility with most plaster-of-paris treatment. Also, such removal of bandages permits of their snug reapplication over the limb and splint, thus producing and maintaining efficient fixation.

The writer recalls the experience narrated by an excellent surgeon at a medical meeting a short time ago, in which he told of a case of simple fracture done up in plaster. Everything apparently went on well, it being particularly noted that the patient's temperature remained normal, and yet, when the plaster was removed, the man's tibia was projecting through the skin and the limb bathed in pus. This could not have occurred if the case had been treated with wood-fiber splinting as above indicated.

The writer has seen a surgeon at a hospital remove a plaster dressing and find considerable bowing of the leg bones, necessitating a rebreaking of the partially united bones with great pain to the patient. In other cases permanent deformities have resulted. Wood-fiber splinting prevents such deformity by the efficiency of its fixation, or permits it to be detected in its incipiency, to the comfort of both patient and surgeon.

2. *Wood-fiber splinting.*—Before stating facts relative to the surgical fixation produced by wood-fiber splinting, a short description of the material and the mode of its application may be of interest. The writer described this material (the results of personal experiments, made in a pulp-mill) at the Milwaukee meeting of the ASSOCIATION in 1893. He was first to advocate its use in surgical splinting (at that meeting and again in a paper read at the Pan-American Medical Congress, Washington, 1893).

The material is made in large sheets, of two thicknesses, to serve all cases of splinting. A splint can be made by cutting a suitably shaped splint-blank from a sheet of the material, moistening it with water and bandaging the moistened splint-form over the part to be splinted. The shape of the blank varies with the case treated. The correct shape for the blank is readily gotten by cutting a paper pattern so as to enfold the parts in the manner we wish the completed splint to enfold them, and then, following this pattern for a guide, by cutting the splint from a sheet of the splint material.

In earlier papers, the writer advised the use of stif-

In this paper the writer will quote the views of eminent surgeons who have written on the treatment of Colles' fracture. It will be seen there has been a considerable change from the earlier days of over treatment to that in vogue at present, when the real nature of the injuries is better known. Sir Astley Cooper, after describing a method of dressing now obsolete, writes: "The arm should be placed in a sling. This position is to be preserved for three weeks in young persons and for four or five in the aged before passive motion be attempted. The recovery in these cases is slow, and six months will sometimes elapse before the motion of the fingers is completely restored."

John H. Packard ("Notes on Fracture of the Upper Extremity," p. 57) writes of a modification of Bond's splint, to which in some cases was added a dorsal splint, each with an elaborate padding of compresses. He says: "Very great care should always be taken to make these compresses of exactly the right thickness, and to lay them over the precise spots at which their effect is needed. An evenly applied bandage, making just the requisite degree of pressure, is necessary to the maintenance of the splint and compresses in their place. And I think that if, as a rule, the apparatus now described were kept on for at least six weeks we should have fewer cases of deformity after those fractures than at present. Often, indeed, I believe it might be retained with a gradual lessening of the size of the compresses for a much longer time, to the great advantage of the patient.

Swinburne ("Treatment of Fracture of Long Bones by Simple Extension," p. 43) employed a straight splint over the back of the forearm and hand, with a pad over the carpus and another near the elbow. The splint was attached to the hand and forearm by adhesive plaster, in a fashion that Swinburne believed produced extension of the parts involved. The writer is dubious of the extension produced by such means, but believes that Swinburne got the fragment into good position by manipulation, and that his simple splint and dressing kept it there. There was no interference with the fingers, and the dressings were discarded sometimes as early as the fifteenth day, generally from twenty-one to twenty-five days. Swinburne reported excellent results.

Bryant ("Manual for the Practice of Surgery," Philadelphia, 1885, p. 992) writes: "(The surgeon) ought to guard against stiff joints in the treatment of those injuries by employing passive movements earlier in the progress of the cases than he has been wont to do."

"After this form of fracture the wrist joint rarely recovers its normal movement, some deformity permanently remaining, and of this the patient ought to be warned" (p. 880).

Moullin ("Surgery," Philadelphia, 1895, p. 413) writes: "It is always necessary to warn patients that Colles' fracture is liable to be followed by stiffness affecting both the fingers and the wrist, especially if there is any tendency to gout or to rheumatism. It is due in many cases to strain and adhesion of the flexor tendons, but it is made worse by rigid confinement. So far as the fingers are concerned it can be generally avoided. Passive motion must be commenced and thoroughly carried out from the first day. With the wrist it is more difficult, but on several occasions I have begun gentle manipulations on the fourth or fifth day with excellent results."

Walsham ("Practical Surgery," p. 427) writes: "Practice passive movement from the third day, as in this form of fracture the tendons, where they cross the back of the radius, the seat of the fracture, are apt to become adherent to their grooves. Remove the splints in about four weeks, and employ shampooing, friction with stimulating liniments, etc., till any stiffness of the joint or fingers has disappeared."

McClelland ("Civil Malpractice," New York, 1877, p. 8) writes: "Notwithstanding the exhibition of the utmost care in the treatment of fractures in the lower third of the forearm, there is always more or less stiffening of the wrist and fingers, a result due, almost, if not entirely, to fibrinous exudations into and around the sheaths of the tendons, and to the adhesions which necessarily follow this fibrinous exudation when the parts are kept at rest for a long time."

Professor Agnew (*Clinic*, Oct. 25, 1871) said: "Difficulty of motion in the neighborhood of joints was a common sequel of this fracture, and, even under the most careful treatment, was found to exist in a majority of cases. He thought it due, not so much to injury of the joint itself as to adhesions of the tendons over the seat of fracture, by which their play was restricted."

It can thus be seen that, since the recognition by Colles of the real nature of this injury, there has been a marked tendency till within recent years to overtreat it with more or less baneful results. Sir Astley Cooper advised that four or five weeks be let elapse before passive motion, in the aged, be attempted. He remarked that recovery is slow, it sometimes being six months before the finger motions were restored. Agnew, Bryant, Moullin, Walshe and McClelland all recognize that the stiffness of the wrist and fingers is due to fibrinous exudations around the tendon sheaths about the seat of the fracture. Bryant states that passive movements ought to be employed by the surgeon at an earlier period than has been wont; but that time he does not specify.

Moullin advises passive motions of the fingers from the first day, stating that this generally prevents stiffness of them. With the wrist, he states, it is generally more difficult (to prevent stiffness), "but on several occasions I have begun gentle manipulations on the fourth or fifth day with an excellent result." The writer believes that Moullin's very definite instruction in regard to passive movements of the fingers to be begun at once, and of the wrist joint on the fourth or fifth day, is good practice and that it ought to become general. All surgeons probably will agree with Roberts ("Fracture of the Radius," Philadelphia, 1897) that "the displacement (in Colles' fracture) is the result, not of muscular action but of the vulnerating force," and further, that "the muscular surroundings have little to do with the causation or continuance of the distortion." For this reason the fracture, if reduced, has no tendency to again separate. It would seem, therefore, that all that is needful after reduction of the fracture is some simple appliance that will protect the parts from accident during reunition, and that will not interfere with passive motion of the fingers from the first day. Swinburne's practice of many years ago, referred to above, was good, though his explanation of it, by the principle of extension applied to the parts, faulty. The writer in several cases, after reduction, has molded a piece of wood-fiber splint material over the dorsum of the forearm and hand in a semiprone position, the hand in line with the forearm. This, bandaged over the parts, he finds sufficient protection for them. It does not interfere with passive motion of the fingers, and is readily removed and reapplied to permit of passive motion of the wrist joint. It is molded directly over the skin, and requires no padding or compress. In these cases he has carefully caused passive motion of the wrist joint from the fifth day, and discarded the splint on an average of about twenty-one days.

The writer believes that the treatment of Colles' fracture could thus be formulated: 1, Reduction, not always easy; 2, protection by a simple retentive appliance while correct reunition of the bone takes place; 3, passive motion of the fingers from the first day; of the wrist, carefully, from the fifth day.

99 Broadway.

THE PASSING OF PLASTER.

Presented to the Section on Surgery and Anatomy, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY EDWARD A. TRACY, M.D.
BOSTON, MASS.
FELLOW OF THE MASSACHUSETTS MEDICAL SOCIETY.

At the Atlanta meeting of the ASSOCIATION, in a discussion before this Section, Prof. Thomas H. Manley of New York made the statement that "plaster-of-paris, as a routine treatment for fractures, should be discarded." The advanced ground taken by that able surgeon is certainly welcomed by the writer, who believes that plaster-of-paris, as a routine means of surgical fixation is doomed, and that its wane will be rapid because of its inherent defects and of the advantages possessed by its rival, wood-fiber splinting.

It will hardly be gainsaid that at present, particularly in the hospitals, plaster-of-paris holds sway as the routine treatment for most fracture cases. Routine, unless perfection has been reached, is baneful to progress in all fields of human endeavor. It can be so in surgery. Happily, however, in this field of activity, there are willing minds and hands to welcome whatever tends toward improvement in their art, and hence the power of routine is weakened; it can not strangle a new method without a trial by honest observers. It may seem an unimportant point whether plaster-of-paris or something better be used in cases requiring surgical fixation, but fractures are frequent and we shall always have them with us; any amelioration in their treatment or results deserves the attention of the profession.

In this brief article the writer proposes to state facts relative to the use of plaster-of-paris as a means of fixation, and of wood-fiber splinting used for the same purpose. A comparison of these facts will render obvious his reasons for believing that plaster, at no distant time, will be relegated to its proper place, a means of fixation to be employed only when more efficient materials can not be had.

1. *Facts of plaster-of-paris treatment of fractures.*—*a.* Plaster-of-paris is dangerous and sometimes deadly to the encased limb. F. H. Hamilton's testimony on that point is sufficient; many living surgeons can verify it.

b. It does not, as generally supposed, *immobilize the enclosed parts.* A moment's consideration makes one clearly understand how futile it is to expect immobilization of limbs swathed in soft and compressible cotton by a rigid bandage outside the cotton. Supposing the fixation to be efficient at first, it is soon destroyed by subsidence of swelling and, later, by tissue atrophy that always takes place in an idle limb.

c. It is destructive of the joint functions of injured joints, by preventing the timely application of passive motion to them. The timely application of passive motion to injured joints is an important indication in fracture treatment.

d. Plaster dressing prevents the surgeon's ready inspection of the parts treated, a condition not tolerated in an ordinary wound, and which, for as grave reasons, should not be tolerated in fracture cases.

Addenda—Dangers of plaster.—The dangers of plaster dressings can not be emphasized too much. Limbs have been lost by its use. The loss of a limb from any cause is fearful; from such a cause, horrible and indefensible. It could not occur if the treatment of such cases were to apply accurately molded splints retained by bandages, which should be removed daily as a matter of routine, until every iota of danger from pressure be gone. Such removal of bandages is easily and speedily accomplished, and allows the surgeon to *know* the condition of the parts he is treating—an impossibility with most plaster-of-paris treatment. Also, such removal of bandages permits of their snug reapplication over the limb and splint, thus producing and maintaining efficient fixation.

The writer recalls the experience narrated by an excellent surgeon at a medical meeting a short time ago, in which he told of a case of simple fracture done up in plaster. Everything apparently went on well, it being particularly noted that the patient's temperature remained normal, and yet, when the plaster was removed, the man's tibia was projecting through the skin and the limb bathed in pus. This could not have occurred if the case had been treated with wood-fiber splinting as above indicated.

The writer has seen a surgeon at a hospital remove a plaster dressing and find considerable bowing of the leg bones, necessitating a rebreaking of the partially united bones with great pain to the patient. In other cases permanent deformities have resulted. Wood-fiber splinting prevents such deformity by the efficiency of its fixation, or permits it to be detected in its incipiency, to the comfort of both patient and surgeon.

2. *Wood-fiber splinting.*—Before stating facts relative to the surgical fixation produced by wood-fiber splinting, a short description of the material and the mode of its application may be of interest. The writer described this material (the results of personal experiments, made in a pulp-mill) at the Milwaukee meeting of the ASSOCIATION in 1893. He was first to advocate its use in surgical splinting (at that meeting and again in a paper read at the Pan-American Medical Congress, Washington, 1893).

The material is made in large sheets, of two thicknesses, to serve all cases of splinting. A splint can be made by cutting a suitably shaped splint-blank from a sheet of the material, moistening it with water and bandaging the moistened splint-form over the part to be splinted. The shape of the blank varies with the case treated. The correct shape for the blank is readily gotten by cutting a paper pattern so as to enfold the parts in the manner we wish the completed splint to enfold them, and then, following this pattern for a guide, by cutting the splint from a sheet of the splint material.

In earlier papers, the writer advised the use of stiffening solutions, and several were designated, for moistening the material with. Water, however, is all sufficient, the material being made so rigid as to require no added stiffness. In compound fracture cases, a strong corrosive sublimate solution may be used to moisten the splint-blank.

The splint, having been made and applied correctly, will hold the parts to which it is applied in fixation from the moment of its retention by a roller bandage. It should be allowed to dry upon the limb, and after twelve hours the author's practice is to remove it, and then to reapply it, thus getting ocular testimony as to the condition of the parts.

Facts relative to wood-fiber treatment of fracture.—*a.* Wood-fiber is adapted to the treatment of fractures of all the limbs, it being moldable directly upon the patient's limb.

b. It produces immobilization of parts, because molded directly on them and retained thereon, without the intervention of cotton batting, which defeats our object if it be fixation. This efficient immobilization is easily maintained by keeping the roller bandage snugly applied over the resilient splint; thus, subsidence of swelling, or tissue atrophy need not interfere with the fixation produced by wood-fiber material.

c. It permits the surgeon to inspect at any time the fracture he is treating, by the simple unwinding of a roller bandage. The reapplication of the splinting is easy, there being no pads or compresses to become disarranged.

d. This ready removal of the splinting permits the timely application of passive motion to an injured joint. The preservation of the functions of neighboring joints should be a most important consideration in the treatment of fractures. When these joints are not involved in the injury which the limb has suffered, this consideration is not so necessary, for normal joints can be immobilized for a long time without serious damage to their functions. When, however, the joints are injured, and this is frequently the case in fractures, it is a serious matter to immobilize them as is done in the plaster-of-paris treatment. Passive motion of the joints involved at the earliest moment consistent with safety is the imperative indication, for both preservation of function, and the earliest return to normal use of the joint.

e. Wood-fiber material is lighter than any other splinting, and no complaint is heard from the patient because of its weight, even in cases where the hip and knee are together immobilized.

f. Wood-fiber material is strong, rigid and durable; splints made from it having been worn in some cases (hip fixation) for eleven months. The material is porous, clean, and does not irritate the skin; in many cases splints having been worn for weeks immediately in contact with the skin, and without excoriation of the skin resulting.

g. No padding is required with splints molded from wood-fiber material; in most cases it is applied directly over the skin. This is important, for how plaster-of-paris or other material can produce immobilization of the bones in a limb swathed in cotton batting it is hard to comprehend.

h. Wood-fiber material permits of rigid antisepsis in the treatment of compound fractures, both of the wound, always accessible by removal of the bandages, and also of the splint material by moistening it with a strong solution of corrosive sublimate. Plaster-of-paris as ordinarily applied is neither aseptic nor antiseptic.

i. Wood-fiber material is most pervious to X-rays, and does not interfere with fluoroscopy.

j. The mastery of wood-fiber splinting.

This mastery readily comes to one possessing a modicum of mechanical ability and who faithfully follows the simple directions given above. No more skill is required to attain it than is necessary to recognize and manipulate ordinary bone and joint injuries; if the practitioner has not that, he ought to let wood-fiber, plaster-of-paris and such injuries alone.

Besides this modicum of ability, the faithful following of the simple instructions is needful. This is illustrated by the experience of an orthopedist of considerable practice to whom a piece of the splint material was sent to be tried. He soaked the material in a pail of water, though the instructions directed that it "be moistened with water until semiplastic." For a result this gentleman had failure; he frankly acknowledged afterward to the writer, his recognition of the cause of his failure.

Though this mastery of the material were difficult to attain, it would be well worth the effort, for the compensatory complaisance which the practitioner enjoys in the conscious power to be able to splint any case that presents itself, he molding the splint to meet the indications of the individual case. Such splinting is scientific, since it presupposes that the practitioner *knows* the indications that should be met in a given case, and that he knows how to meet them. It contrasts strongly with the employment of manufactured splints, of which there are several varieties on the market, finely formed with beautiful curves and convenient angles; as a rule, however, we find that our patients have not been made to fit these machine made splints. An appreciation of this and of the practicability of employing wood-fiber led H. O. Marcy to state the rule, which it is believed will yet govern this branch of surgery, "The surgeon must make a splint to fit the limb, not the limb to the splint."

A demonstration of the practicability of living up to this rule is furnished in the splints here shown, each of which was molded directly upon the limb of the patient treated, and made of wood-fiber material moistened with water.

(Splints shown were used upon patients for fixation of the toes, ankle, bones of the leg, knee, hip, hip and knee together, thumb, fingers, wrist, bones of the arm and forearm, the elbow and the shoulder.)

In conclusion, the writer does not imagine that his poor efforts can change the general practice in the treatment of fractures much; but he hopes that some day the masters will cease for awhile their labor of climbing the Olympian heights of surgery to consider the facts of this fracture-treatment question. Their teaching, ultimately, he doubts not, will break the sway of the plaster idol, to the comfort and betterment of the injured.

99 Broadway.

DISCUSSION.

Dr. McFarland of Pittsburg—I agree with the author in the treatment of Colles' fracture, but I can not coincide with him in so far as plaster of paris is concerned. We owe too much to it to discard it. The author laid much stress upon the cotton padding, but so far as my experience goes with fractures of the lower extremities the ordinary Buck's extension apparatus and the sand bag work very well. When the limb is in apposition and there is no disposition to displacement we apply plaster-of-paris. So far as the cotton is concerned, we put it on with an ordinary roller bandage. It is very thin and will apply itself accurately to the contour of the limb just as well as wood fiber. Even in compound fracture it is possible to do very excellent work with plaster. It is inexpensive and to one who is familiar with it, it is not difficult to apply. Its weight does not enter greatly into the matter. With reference to the ambulatory treatment you must use plaster-of-paris, and it gives us good results. Plaster-of paris has stood the test of time.

Dr. McConnell of Pennsylvania—The author objects to plaster of-paris because it does not immobilize the joint that is injured. I think a number of the bad joints that we have today are due to the too early commencement of passive motion. I think I would be opposed to plaster-of-paris if I used it the way they do in Boston. I do not put cotton batting next to the limb and I believe a very few of us do. We apply a piece of canton flannel first, then four or five folds of plaster-of-paris bandage, placing the soft part of the flannel next to the skin. On the outside of the plaster we place another piece of the flannel. When we want to examine the limb we can take the anterior part off for this purpose. I do not think there is anything against plaster-of-paris, but the fault is the lack of brains of the operator.

Dr. Murray of Michigan—I have used plaster considerably, and have also used silicate of soda, especially in compound fractures. I take the injured limb, measure the limb of a well child of about the same size, make my plaster of-paris bandage over the limb of the healthy child, and after a few hours remove it and apply it to the injured limb. I apply the plaster to the under surface and hold it in place with adhesive plaster. This makes a light plaster and the person can walk around with perfect ease. To my mind the silicate is better than plaster-of-paris. So far as thickness is concerned, from four to six bandages are sufficient. Any old piece of cotton that you can find around the house will answer for the purpose. You can apply it at once in any ordinary fracture, or the second day after you have made your bandage over a healthy limb.

Dr. R. H. Sayre—I would like to say a word about Dr. Swinburne's method of making extension of the fragments. He would apply plaster upon your arm and make traction upon the hand until he has the bone adjusted. The great point in the treatment of a fracture is to reduce the bone first. He would then reverse the two ends of his adhesive plaster, so as to hold the bone in position. With regard to the question of plaster-of-paris, I think a great deal of unjust blame has been put upon it by the reader. It seems to me the blame should be put upon the surgeons who apply it. Concerning the statement that plaster-of-paris has caused limbs to be lost, the sloughing which has occurred took place before the application of the plaster or the blood supply was suddenly interfered with. If the plaster was not put on too tight there would be no sloughing. A simple string around the finger will stop the circulation and bring on sloughing, and silicate of soda or anything else will do the same thing when improperly applied. It is said that plaster-of-paris does not immobilize the joint, but that depends upon the way in which it is put on. If you have a very fat woman with very small bones and you put on plaster-of paris, unless you tie it down her bone will certainly wobble. If you put the plaster on outside of the stocking it will often answer perfectly well. Instead of taking six hours to dry, it takes but fifteen minutes. With a jack knife you can cut it from one end to the other and take it off at your pleasure. If the case is a very fat one you can remove a sufficient slice from each side and thus make it fit admirably. In some cases you want more resistance than this particular kind of splint will give you. I have never seen a leg like these splints seem to have been applied over. This material is excellent and is lighter than plaster-of paris, which is an advantage, but I think it is unjust to speak against any material that may be used, if the fault is in the mode of applying and not with the material itself. Regarding the advantages claimed for this material, the plaster-of-paris seems to have the same advantages.

Dr. McClelland of Ohio—I have used this material in my practice for many years, but I now use plaster-of paris more than ever. Other surgeons in my town have used both. I agree with our Chairman that the trouble seems to be more in the way the surgeon handles the case than the material. Sometimes bad-results will follow, no matter what the material that is used.

Dr. Hill of Vermont—One of the great advantages in the applying of plaster-of-paris is that you need not handle the broken limb. To persons who are nervous, this is certainly a great advantage. Another good point is that we see our fractures come out of the plaster in good condition. This is due largely to the fact that nature has been left entirely alone and given an opportunity to complete her work. It is often difficult in the country to hold a limb in exact juxtaposition. We owe a great deal to plaster, for we need not feel anxious after we have properly applied it.

Dr. J. McFadden Gaston of Atlanta—If the bone is kept too quiet we sometimes fail to get good results, and this is especially true where the plaster-of-paris is applied under certain conditions. I sometimes rub the ends of the bone together so as to set up an inflammation, and then put on the plaster afterward. I always leave an opening in the plaster so that the limb may be inspected. Pasteboard splints are most admirable substitutes for plaster-of-paris. Silicate of soda is the most admirable dressing. It makes a light splint and is well adapted to all fractures. It can be applied at any time. In discussing the use of splints, we must not forget that the two leading parts in the treatment of fractures is first, to properly reduce them, and second, to keep them reduced.

Dr. G. G. Davis of Philadelphia—Silicate of soda bandage is very good, but it must be used in a certain way. I prepare my bandages by means of a bandage roller. I make a V-shaped box with a handle at the top and a ledge near the bottom. This box is filled with silicate. The bandage goes over the edge of the box and is wound on the winch. Bandages made in this way will keep indefinitely and are always ready for use. This is especially advantageous for those who do not have ready access to a drug store. When I take them out I roll them up in wax paper. In applying them I simply put a layer of cotton next to the limb and then put on one of these silicate bandages. I use strips of rubber or something like that to prevent the bandage from wrinkling. I then apply additional silicate but not too much, and after this another bandage is applied. The leg is allowed to remain on the surface of the clothes, and the next morning the bandages are dry and hard. You can readily make openings in this if you wish to remove it. If you wish to reapply one of these dressings as is frequently desirable in the after-treatment you can very easily do so. This method also does very well for a brace for a child. It can also be applied in such a way that it may be laced with a corset string so that it can be taken on or off at will. By applying shellac they are made much more durable. You must adapt your dressing to your case, and I do not think plaster-of-paris is as well adapted for this treatment as the silicate.

Dr. Fowler—The fact is that about three-quarters of malpractice suits are brought for bad results following the treatment of fractures. It is important to be able to inspect the injured parts after the bandage is applied, but this is not an objection to plaster-of-paris. In many instances bad results are due to carelessness of the patients. Plaster-of-paris and pasteboard might be employed together, or at different stages both may be used alternately. This is a subject too vast to be discussed fully here. The use of silicate of soda is open to the objection that unless there is something to hold it in place it is almost impossible to prevent the distortion of the parts and the occurrence of unsightly and uncomfortable wrinkles. An attempt has been made to make a spinal jacket of silicate of soda and the result was the combining together of silicate of soda and plaster-of-paris. The method is to first apply an ordinary silicate of soda dressing and over this a dry bandage; then the plaster-of-paris is applied. This is allowed to stay until the silicate of soda is hardened, probably some days. At the end of this time the plaster-of-paris is cut away and the silicate of soda then assumes the entire responsibility. It is useful in some cases where the person is weak and broken down by disease. Without the plaster of-paris it would not have been possible to achieve success in the treatment of fracture, and without this substance and and also silicate of soda, pasteboard, etc., it would have been absolutely impossible to have been successful in the ambulatory treatment.

Dr. Tracy—It has been urged against my method of wood-fiber splinting that it could not be used in the ambulatory treatment of fractures. In answer to this objection, I am happy to state that a case of fracture of both leg bones near the ankle treated successfully with wood-fiber, ambulatory treatment was reported by me before the New York Society of Medical Progress, in March last. The use of passive motion to injured joints is advocated at the earliest moment consistent with safety. The surgeon treating a case must be the judge of that time. In this discussion, not indeed anticipated, statements have been attributed to me which will not be found in my paper and I feel that when it is read at leisure by the members that they will be more likely to agree with me in the conclusions arrived therein. Reference has been made to the use of silicate in the treatment of spinal troubles. The spinal jacket which I now exhibit to you was molded directly upon

d—a patient of the Boston Children's Hospital, a case of Pott's disease—and worn by the child during the past year. This was done through the courtesy of Dr. Bradford of Boston. The jacket is made from wood-fiber material and, as has been said, was molded directly upon the child, without the aid of the plaster cast used in the ordinary method. This direct molding was possible with the aid of my machine for the control of the spine, by which traction in any desired degree, together with lordosis of the spine can be produced simultaneously. [The machine is described and pictured in the Boston *Medical and Surgical Journal*, Oct. 1, 1896.]

In conclusion, I would state that no other gentleman present has used the wood-fiber splinting described in the paper, and for that reason more words in its favor are wanting. The material referred to by Dr. McClelland is not the same as that which I have exhibited to you.

RENAL SUPPURATION, CATARRHAL, SPECIFIC AND TRAUMATIC, AND THE VALUE OF MICRO-URANALYSIS OF THE URINARY SEDIMENT AS AN AID TO DEFINITE DIAGNOSIS OF IT.

Presented to the Section on Obstetrics and Diseases of Women, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY THOMAS H. MANLEY, M.D.
PROFESSOR OF SURGERY, NEW YORK SCHOOL OF CLINICAL MEDICINE. NEW YORK.

(*Concluded from page 990.*)

The morphologic examination of urinary sediment as an aid of dominant importance in the diagnosis of renal suppuration.—Renal abscess or ulceration of the kidney has only comparatively recently been added to the nosology of serious pathologic lesions. Its ready and definite recognition, with an accurate knowledge of its etiology, with our modern precise and effective treatment of it, makes one of the grandest achievements of the art and science of surgery in the nineteenth century.

For a long time past, for say thirty or thirty-five years, since, in fact, the study of the histologic elements of the human body began to assume the aspect of a science, more or less importance has been attached to the significance of the morphologic elements found in the urinary sediment, as an important though indefinite auxiliary in the diagnosis of renal suppuration.

M. Alberan was among the first to utilize this aid in the diagnosis of tuberculous kidney, and his distinguished master, M. Guyon, has long since admitted the great semiologic value of uranalysis in suspected renal abscess. In the colossal work, however, of systematically arranging, grouping and classifying the different varieties of pyuria, the late Dr. Carl Heitzman was the pioneer and founder. As early as 1879 we find his first contribution on this important subject; but for some years before his death—January, 1897—he had placed it on a solid and enduring basis, and for this alone he has left the medical profession under eternal obligations to him.

Anatomic and pathologic data.—In order that one may intelligently interpret the morphologic atoms found in pyuria, it is essential that we have a familiar acquaintance with the finer anatomic atoms and the structural composition of the genito-urinary tract, besides the difference in function and histologic composition in the two sexes.

Pathology and urinary analysis.—It goes without saying, that, besides a knowledge of the normal structures and secretions, we must be acquainted with the anatomy and histology of the urinary organs before we undertake a microscopic examination of the diseased elements found in the sediment of the renal excretion. We must have a special training in urinary analysis; as a general knowledge of the microscope will serve us but an indifferent purpose when we come to purulent urine. It is important, then, that there be a clear understanding on this point at the outset, else chagrin and disappointment are quite certain to follow.

The urine in renal suppuration, or purulent catarrh.—In order that we may eliminate error or confusion as far as possible, in all cases, it is well to exclude suppurative conditions along the lower genito-urinary tract; the vagina, the uterus, the Fallopian tubes or the urethra; and in the male, the urethra, the prostate or the seminal vesicles.

Having excluded these, as free, we next approach the bladder. For various reasons we meet with many difficulties here; not in recognizing the presence of cystitis, but its various types.

The urinary sediment.—It has already been stated that the presence or absence of renal pus in the urine, of itself, under many circumstances, is an indefinite quantity in diagnosis.

Thus, in chronic catarrhal nephritis in strumous individuals, epithelial degeneration and morphologic reversion of histologic elements and suppurative discharge, so-called leucocytosis, may go on over a long period without hyaline degeneration, interstitial or organic changes in the renal substance supervening. Neubauer and Vogel record a case bearing on this point, which very well demonstrates the tolerance of the system to pyuria in certain individuals. Their patient was a man who was under treatment for rheumatism, when it was accidentally discovered that he was periodically discharging great quantities of pus in the urine. And yet there was no evidence of any lesion along the uropoetic tract.

Suppurative or ulcerative inflammation of the peripheral type, involving the surface layers of the epithelia or the mucosum of any area of the mucous membrane of the urinary tract up into the tubular structures of the kidney, always gives issue to a purulent admixture of the sediment in the urine.

But when we have an infection involving the interstitial connective tissue elements in the renal tissues, we may have a large purulent collection, without any of it making its way out through the urinary passages. The same absence of pus in the urinary sediment may obtain in cases of calculous impaction of the ureter, or cicatricial stenosis consecutive to ulceration.

The composition of the urinary sediment in purulent urine.—Aside from mineral and nitrogenized elements in pyuria, in the sexes, we have invariably epithelial elements, pus corpuscles, shreds of disintegrated connective tissue, and commonly more or less blood discs, according to the degree and site of inflammatory action.

Large quantities of pus in the urine, of a vesical or renal origin, *is always more or less ammoniacal.* This decomposing animal matter greatly accelerates fermentation of the healthy secretion, and this in turn imparts an *alkaline reaction* which, acting on the urine, induces again a *saponification*, a transformation of pus into a ropy, tenacious mucus. This chemic change is more common in some specimens of urine than in others; its degree depending on extent of urinary stagnation as well as the condition of the mucous membrane of the bladder; and hence there may be discharged from the weakened, anesthesic bladders of old people urine primarily, freely intermixed with pus, yet on examination but few or no pus corpuscles can be found.

Periodic admixture of pus in the urinary sediment.—In every variety of pathologic lesion along the genito-urinary tract, attended with issue of pus, its presence in the urine is very intermittent, as are also the proportion of epithelial elements, and the seminal and proteid substances discharged.

This is a striking characteristic and an important feature to note in pyuria of every description, but in none is it so constant and striking as that of a renal or vesical origin.

In abscess of the kidney, in pyonephrosis and pyelitis, pus may be discharged with the urine only at considerable intervals of time. But when the patient is suddenly seized with violent colicky pains polyuria, vesical tenesmus and cystic irritation follow, pus flows off with the urine in great quantities. Relief succeeds and pus disappears from the urine, sometimes completely, for several months at a time. The same phenomenon may be observed in pyelonephrosis. In pyelitis of a catarrhal origin, intermittency of pyuria is one of its most salient clinical features, the purulent escape being largely influenced, or at least temporarily suppressed, by the effects of exercise, diet or exposure.

The varieties of pyuria. Anatomic.—Pyuria from the standpoint of anatomy may be divided into: 1. Urethral. 2. Cystic. 3. Renal.

Pathologically, we have, in their order of frequency: 1. Infection: *a*, tubular, by the mucous membrane, ascending, the most common; *b*, by the blood vessels, vascular, or descending. 2. From mechanical and chemic influences; from the extravasation of blood lithiasis, or any description of obstruction, by stricture, neoplasm or other physical impediment.

The most common type of purulent urine is urethral of a specific origin. This is readily differentiated, both by clinical evidence and simple tests. But when we have suppurative catarrh of the deep urethra there is a back-flow into the bladder, which may or may not provoke a septic cystitis.

It therefore follows, when we have infection from extrinsic sources, we may have a coexistent inflammation of the bladder with a urethritis, which will yield mixed morphologic elements, when the definite isolation of one from the other is impossible, except by a careful microscopic examination.

Hyperacidity of the urine is a well-known cause of vesical or urethral irritation; the pungent urine acting with great energy on the surface epithelia. In a similar manner do we have that most distressing type of chronic cystitis, consecutive to intrinsic renal suppuration of the kidney; when, again, we have simultaneously discharged with purulent urine an admixture of the finer anatomic elements of both the kidney and the bladder. It has not been my experience that urethritis is a concomitant lesion with chronic renal suppuration. The urethral mucous membrane seems to resist the invasion of pathogenic microbes which act with great energy in the kidney or bladder. But we have evidence, from ultimate pathologic changes and other reliable data, that in all cases of renal suppuration the loose vascular mucous membrane of the ureter on the side involved is the seat of inflammatory changes.

Descending ureteral infection succeeded by the draining away of pent-up ammoniacal urine, in time leads to destruction of the surface layer of the ureteral mucous membrane, to patches of erosion, submucous induration, or atrophic changes and great dilatation on either the renal or vesical end. And again, we find in the records, some rare cases of pyonephrosis, in which the ureter on the affected side throughout its entire extent is enormously dilated.

This was most conspicuous in one of Dr. Myles' cases. Speaking of the ureter, as found on autopsy in one of his fatal cases, he says: "It was greatly dilated; below it was about the size of the small intestine, rapidly enlarging from below upward; at its pelvis it was fully equal in size to one of the sacculi of the colon. It formed a huge pear-shaped reservoir for the urine, evidently acting as a supplementary bladder."

It is in this class of advanced destruction of the histologic elements of the kidney, the ureter or the bladder, that a morphologic examination of the urinary sediment alone will not always reveal the exact seat of pathologic changes, or rather, where they began.

From the foregoing it is clearly apparent that pure unmixed renal pus is seldom found in the urine; that from the bladder or ureter being generally intermixed with other elements. The special features of the purulent products of balanitis, urethritis or the prostate can not be considered here. Our investigation must be restricted practically to the bladder, the ureter and the kidney; for though we may have uncomplicated suppurative cystitis, clinical and morphologic evidences point to the conclusion, that in all severe or protracted forms of renal suppuration, cystitis is invariably a concomitant condition.

It is highly important to always note the difference of the sexes in the qualitive analysis of pathologic urinary sediments, and in all cases of suspected renal suppuration in women to be certain that we eliminate the accidental admixture of muco-purulent discharge through the vulva from catarrhal or ulcerative conditions of the mucous membrane of the vagina, the the cervix, the endometrium or the Fallopian tubes.

When any of these conditions co-exist with renal disease, the only means by which we can exclude their inflammatory elements from intermingling with the urine is by drawing it directly from the bladder. Catheterization of the female bladder, however, should not be employed as an *en courant* procedure, or in any instance, unless cystitis already exists.

It is true that a microscopic examination in experienced hands will readily exclude uterine or vaginal inflammation, but with discharges from the tubes there remains some doubt. We may generally exclude every description of urethral pus from the urine of the male, by catheterization.

The urethra may be first irrigated, then the catheter is introduced. As the mucous membrane of the bladder in the male is altogether more tolerant than in the female, we may have but little fear of subsequent cystitis, provided clean tubes are employed.

Some authors advise, in doubtful cases, that the patient retain the urine as long as possible, then having passed off the first half the second is collected, which if it exhibit pus it must necessarily be from the bladder or a source above; but this is a fallacy, of practically no value whatever in obscure or doubtful cases. In most laboratories but little if any consideration is given, as to how the urine is collected, as some microscopists claim to be able to decide the source of all urinary sediment by their morphologic character alone. It is my opinion and belief, nevertheless, that this is a mistake, for while conceding the present marvelous perfection of morphologic uranalysis it by no means follows, that we should not obviate as far as possible every source of error or confusion.

The diagnostic significance of anatomic elements in the urinary sediment of renal suppuration.—The presence of the detached epithelial elements in pyuria definitely stamps its origin. In the near past it was regarded a great advance when the microscope with unerring precision revealed the presence of papilloma, of epithelioma and ulcer of the bladder, but now morphologic science has widened the field of diagnosis far beyond the dream of the most sanguine.

The *modus operandi*, the technique and knowledge of the art of microscopic uranalysis is too large to enter into here. It is quite enough to again repeat in this connection, that the knowledge of the average microscopist will be of little value to him, without special training, opportunities and experience.

Ambitious, enthusiastic investigators have not stopped at the study of the histologic elements of the urine, blood, pus, epithelia and the structural elements, but have now utilized their knowledge in ferreting out the specific character of the various lesions along the urinary tract, by isolating their characteristic microbic elements, the pathogenic and non-pathogenic.

For a complete study of the more ordinary infections of the genito-urinary organs the reader is referred to the excellent monograph of Mechoir.

Ammoniacal or putrid urine.—In ammoniacal purulent urine the tableau is completely altered, for not only are new salts generated, but also the purulent constituents of the urine are radically altered, and besides, albumin or some chemic substance analogous to it is invariably present.

Morphologically speaking, we sometimes have in this type of pyuria, a quite complete absence of unbroken pus corpuscles, these having undergone disintegration and saponification by the pungent ammoniacal alkali in the bladder.

As the patient voids this urine we may find it highly charged by a tough ropy mucus, with no pus; but if we wash out the bladder and later catheterize, an abundance of unchanged purulent deposit will be found. This, as will be understood, applies only to those cases in which the pus has not been pent up in the renal pelvis, or an abscess cavity, and there is a free unimpeded drain of it off by the passages.

Albumin in the urine and acid urine.—Before fermentation begins in urine of acid reaction, when properly preserved, we will find no other evidence of molecular disintegration of the cells than that dependent on disease.

In strongly acid urine the pus is commonly found lying in coagulated flocculi, the superabundant fluid above being clear and transparent.

In this description of purulent urine we will sometimes find a complete absence of albumin. Most authors maintain that purulent urine is albuminous, which no doubt is correct of the ammoniated and purulent; but in one case under my care last winter (1896–97) of the most aggravated renal pyuria, in a considerable number of the specimens examined albumin was entirely absent. This was probably the result of fresh pus being discharged immediately on reaching the bladder before putrid changes began.

It is well to remember then that the absence of albumin as determined by the chemic test is no proof that pus is not present.

This may also be verified in the case of a physician recently under my care, who had a purulent kidney on he right side.

As we may well expect, the organic changes in the histologic elements of the urine when putrescent decomposition has begun are very well pronounced. In all these cases septic infection has spread to the bladder, when there is an exfoliation of pavement or cuboidal epithelia, or in places ulceration may penetrate all the strata of the epithelia and involve the vascular layers of the submucosum.

CASES ILLUSTRATIVE OF THE VALUE OF MORPHOLOGICAL URANALYSIS AS A MEANS OF DIFFERENTIAL DIAGNOSIS IN RENO-VESICAL LESIONS.

Case 1.—Appendicitis with ulceration into bladder; history.—J. S., male, 36 years old, liquor dealer, married. Had a soft chancre when 22 years old; later had syphilis. Four years previously, while serving as a sailor, patient was taken, in Bermuda, with inflammation of the bowels. From this he slowly recovered, though for some time after being about had trouble voiding his urine; but after about six months this passed off. One week before I saw him he was seized with severe pain in the right side, with chills and fever. The usual domestic remedies were applied, when on the fourth or fifth day the pain in the abdomen moderated, but his former bladder trouble again commenced. When he came under my notice his general condition was very bad. He had high fever, with exhaustive sweats, little or no sleep and great exhaustion. His vesical trouble was distressing, requiring almost constant straining in urination. He had a tympanitic abdomen with marked tenderness over the hypogastrium, the right iliac fossa, and further up over the ascending colon.

The clinical features of this case, in several striking particulars, pointed to pyelonephrosis. The primary fulness in the flank, which we may look for in displaced, enlarged, purulent kidney; the polyuria, with abundant discharge of muco-purulent material in the urine, all rather inclined to the possibility of renal abscess. On the other hand, the abdominal condition, tympanites, etc., lead one to suspect a recurrent appendicitis with probable discharge of abscess into the bladder. In order to determine the source of the pyuria, uranalysis was made of the urine, showing, specific gravity, 1.030; alkaline reaction; no sugar; slight shade of albumin present.

Microscopic examination: Pus corpuscles were abundant and surface bladder epithelia; a few blood discs, shreds of connective tissue, with crystals of margaric acid, cholesterin, particles of undigested muscle fiber, fat and starch globules. This examination, then, decided beyond question the fecal admixture in the urine. It was then advised that an operation be immediately performed to drain the pus out, by a free incision in the abdominal wall. The family physician, Dr. Thos. Kelly, was not in accord with me on the presence of appendicitis, yet consented to and kindly assisted me in the operation. On free incision the base of the cecum was reached, when a vast abscess cavity was opened, widely distended with pus and feculent matter. No search was made for the appendix. A wide breach was made for free drainage. From this time the vesical symptoms commenced to yield, and within a week the urine cleared up and micturition was again normal.

In the above case the incipient and spasmodic pain in the side, with localized tumefaction and marked tenderness up along the ureter to the kidney, disappearing, in a large measure, with the advent of the large discharge of pus by the urine would lead one to infer renal abscess. The tumefaction of the abdomen might also have proceeded from a propagation of infection through the perinephric tissues.

Case 2.—Cancer of sigmoid flexure, with invasion of bladder; history.—About three years ago I was invited by Dr. S. Waterman, of New York, to see an aged physician suffering from a most distressing cystitis. The patient was 76 years old, and for some years past had suffered from prostatic tumefaction and vesical irritation. When I saw him he had high temperature, was much emaciated and suffering great pain in the hypogastrium, especially on urination, which was frequent, especially at night. It was learned that he had had a most aggravated form of constipation for the preceding years; but now diarrhea was nearly constant and sometimes there was fecal incontinence; but he assured me his bowels were "well enough" if we could only relieve the bladder. On examination a large mass was detected in the left inguinal fossa, extending up along the descending colon. This was quite hard and insensitive to moderate pressure. The hypogastrium was highly sensitive and there was evidence of considerable vesical distension. He was obliged to introduce the catheter to draw off the urine, which was daily becoming more and more highly charged with mucus and more difficult to drain off. By rectal examination it was found that the prostate was but little enlarged, and that in one lateral lobe only. Carrying the finger further up, to the point of the peritoneal reflexion, a hard nodulated mass was found impacting the lumen of the rectum. It was clearly evident, therefore, that we had an impaction of the sigmoid flexure of the colon, with mechanical impediment from a neoplasm, the weighted over-expanded bowel falling over forward and compressing the bladder walls. Microscopic examination of the urine, as in the preceding case, exhibited much pus, the detritus of decomposing ammoniacal changes, with a large number of blood discs and fecal elements. This provided us with conclusive proof that the growth in the intestinal wall was malignant, and that it advanced forward over the recto-vesical septum and opened a communication with the bladder.

In this case, morphologic examination having decided definite diagnosis, we were enabled to advise appropriate measures for relief. The day following I performed Madyl's operation for an artificial anus. The relief of the vesical symptoms following was most gratifying. By keeping the bladder well irrigated and drained by the urethra much relief and comfort was enjoyed, until the diffusion of the cancer elements, three months later, choked up the ureters and induced fatal uremic poisoning.

Case 3.—Fecal impaction of sigmoid flexus; history.—Four years ago last April Dr. Wm. S. Gaudineer of New York requested me to see a young woman who a few days before had an abortion, and was, among other things, suffering from severe cystitis, with a large fulness in the left groin. The Doctor brought a specimen of the urine when he came for me. A chemic and microscopic examination of it precluded any possibility of a suppurative lesion of the bladder or kidney. The urine was highly acid and slightly clouded with mucus, but contained few pus corpuscles and few epithelia. When I arrived at the home of the patient I learned that she was unmarried, and that she had probably provoked the miscarriage herself. She had a temperature of 104 degrees, with a quick pulse, considerable thirst and nausea. It appeared that after the fetus came away catheterization was found necessary, but this was immediately succeeded by a painful cystitis.

The abdomen was tympanitic and everywhere sensitive. On the left side, rather inward toward the median line, there was a distinct fulness. On questioning the patient closely, it was learned that she had had no movement for ten days, although she said that this was of no consequence, as she had often gone two weeks without a motion. As she was everywhere sensitive, in the vagina as well as externally, it was decided to anesthetize, place her on a table, and then examine with the abdominal muscles relaxed. By bimanual examination it was easier to outline the mass in the pelvis, which by exclusion we decided was probably a fecal accumulation.

It was agreed that we should again see the patient the following day if there was no improvement, but that evening, within an hour after we left, the patient had an enormous alvine evacuation, which was followed by relief of all her symptoms.

In this case, although the symptoms pointing to renal or vesical lesion, *ab initio*, were not prominent, yet some features of her history suggested this possibility. She had once had gonorrhea, and later had been told that she had a displaced kidney, circumstances by no means to be overlooked in pelvic inflammation, but uranalysis eliminated both decisively, at least as causative or consecutive to pyonephrosis.

Case 4.—Intermittent pyelonephrosis; right side.—Three years ago a case of renal suppuration came under my care which presented several quite unique features.

History.—Patient a female, single, virtuous, 24 years old; both parents died of pulmonary tuberculosis. She enjoyed good health until one year before, when she became sensible of a fulness in the right lumbar region, advancing forward. Soon after this she was seized with severe sciatica in the affected side. For nearly three weeks this persisted in a severe form, when one night while in bed she was suddenly taken with severe cramps and colicky pains in right side of abdomen. After taking hot drinks and freely using fomentations, the pain gradually subsided, but free urination began, and she alleged that during the next twenty-four hours she passed nearly a gallon of a thick milky colored urine.

At the time she came under my notice she was in fairly good health; she had a fair muscular development, but was rather pale. The temperature was but 100 degrees, and the pulse but slightly accelerated. The bowels were regular, and she was passing a normal quantity of pale, limpid urine. She complained of having suffered from leucorrhea off and on for the past ten years. On examination of the abdomen, a well-defined fulness was apparent on the right side, impinging forward and slightly downward. When she assumed the prone position this tumor could be recognized only by the sense of touch on palpation, which every time, on deep pressure, provoked a desire to urinate. As she lay on her back it was possible to move the mass slightly in an inward and outward direction.

As the symptoms present implied no urgency in treatment, palliative measures only were recommended. Some of the urine passed that day I was enabled to secure for examination. It was of an acid reaction, and contained no albumin or sugar. Under the microscope, besides the ordinary visceral sediment, pus corpuscles and renal epithelia were found; but few surface pavement epithelia were present.

Two days later she commenced to pass pus in large quantities with the urine. On examination of this, the change noted was most extraordinary. The consistence was nearly that of gruel. Reaction was strongly alkaline, and the urine emitted a sharp ammoniacal odor. This discharge continued four days. From this time the purulent and epithelial elements became more scanty, and in ten days had disappeared. It is needless to add that with abundant pyuria the tumor in the loin commenced to recede, and finally vanished.

In this instance, the underlying pathologic process was tubercular. Its clinical features pointed quite conclusively in that direction, though I have been lately informed that she is now well, and never had another attack since; a circumstance, too, peculiar to that mysterious malady, which sometimes for years remains latent, again carries one to death's door, to undergo arrest, with recrudescence perchance, after years, or never in one's lifetime give further trouble in the affected organ.

This is the only instance of recovery from pyelonephrosis which I have observed in women.

Case 5.—Pyelonephrosis; chronic; right side; history.—Patient, 50 years old, married, of a rather slight build, but considerable endurance. Followed the occupation of a seamstress before and after marriage, and had one child, now grown. She first came under my care four years ago, for treatment of irritable ovary on right side. I then lost sight of her, until August, 1896, when I was called to attend her for a very painful form of cystitis. At this time, she had become greatly wasted, anemic, care worn and melancholy. She was practically a confirmed invalid, but by dint of an undaunted spirit managed to keep about a part of the time. She had in vain tried regular, irregular and quack practitioners, but without any permanent relief.

Realizing that the case was a grave one, I made a very complete examination of the general system and the organs.

She had a low grade of fever with thirst, no appetite and no rest. Vesical strangury and vesical tenesmus made her life one of constant torture. The wasted state of the body rendered an examination of the organs an easy matter, as everywhere over the spine and hips the angular curves of the bones stood out prominently under the integument.

Exclusive of the vesical territory, which was a constant source of uneasiness, she complained of occasional darts of a burning pain up along the course of the ureter over the crest of the right ilium. Down in the iliac fossa on the same side, on moderately deep pressure, there was experienced a sense of soreness and pain, and a little further up a movable mass, could be detected. By vaginal examination nothing definitely was reached except extreme sensitiveness of a contracted thickened bladder and an impacted rectum. No evidence of any lesion on the left side of the abdomen or pelvis could be discovered. Thorough clearing of the colon afforded some relief, but the painful polyuria persisted with evidence of marked constitutional disturbance. There was nothing in her history elicited that suggested her ever having had an attack of gonorrhea. Nor was there any evidence of visceral tuberculosis except, possibly, along the urinary tract; nor was there anything pointing to rheumatism or gout. She micturated as often as twenty to thirty times in twenty-four hours; even then, in the warm weather of our New York summer. Every discharge of urine was blended with pus and mucus.

Microscopic examination revealed the presence of abundant leucocytes, renal and bladder, epithelia, with other evidences of abscess and ulceration. She manifested a positive repugnance to any surgical operation at first, and for the following four months continued to suffer from vesical distress and constitutional exhaustion. Finally, when her general condition became desperate, she insisted on relief by any means possible.

On operation it was found that the right kidney had descended to the iliac fossa. It was nearly as large as the fetal head. After removal, on transverse section it was seen that but a thin layer of the cortical substance remained, all the secreting tissue having been replaced by very large loculi of thick purulent material. There were no calculous elements found.

This case was one, in which the morphologic examination of the urine, again, established beyond question, the precise character and location of the pathologic process. Repeated uranalysis in this instance too, exposed many of the fallacies current in many of the text-books, on the chemic and anatomic elements found in pyuria, *e.g.*, that very purulent urine is always alkalin, that renal epithelia are present only in the early stages, or only when the pus corpuscles are relatively scarce. I might add, in this as in others of the same class, that repeated attacks of severe sciatic pain were experienced in the advanced stages of the disease.

Cases 6, 7 and 8.—Unilateral pyelonephrosis; lithiasis -As these three cases belong to the same class the salient features of all may be described together.

History. - One was a physician of robust physique, 35 years old; one was a cabman, 33 years old; one was a grocer, 40 years old. All were married and all were steady but not heavy drinkers of malted light liquors. In all, the right kidney was the one involved. Except the renal trouble all enjoyed good health. In all, their attacks were intermittent; at times there being intervals of several months without any discomfort whatever being experienced.

In all, their attacks were of an extremely acute type, the spasms of pain at the outset being of a most agonizing character. But when polyuria and pyuria set in, relief came and remained. In all these cases at the outset of the attack there was marked fulness, muscular rigidity and tenderness over the renal areas of the side involved. In *none* was there anything more than slight and transient cystitis. All at various times had passed oxalate of lime or uric acid calculi.

Chemic and morphologic analysis of the urine. In these cases, at the outset of the attacks the urine was strongly acid, then feebly acid or neutral, to again, after a few days, become acid. In all, in the early stages, when sanguinous admixture of the urine was marked, sero albumin was present; but as the blood globules disappeared and leucocytosis set in, after the sediments were well settled, the decanted urine contained no albumin. Early microscopic analysis in all cases, exposed two distinct classes of physiologico-pathologic substances, *non-inflammatory* and *inflammatory*. I. An excess of mineral elements, the crystals of oxalates and urates, with a free admixture of coagulated fibrin and blood corpuscles. In some urinary evacuations the quantity of mineral sediments and detritus was very large for the first or second twenty-four hours. 2. After the intensity of the attack passed off the febrile reaction of the system was attended with free leucocytosis and the shedding of renal casts and epithelia, none except the surface layer of pavement epithelia of the bladder, were present in urinary sediment.

The three cases above were typical and illustrative of *periodic* pyelonephrosis dependent on urinary excretions, uric acid or oxalate of lime or the phosphate, primarily in the tubules of the cortex, then entering the pelvis to become later engaged in the ureter.

The volume of some of the calculous masses which make their way down to the bladder demonstrate the remarkable expansive properties of the healthy ureter. It is possible that the passage of these not only provokes the agonizing pain of renal colic, but also mechanically produces an erosion of the innermost strata of epithelia, a contusion of the deeper submucous, vascular layer of connective tissue, or even a laceration in places completely through the mucous investment.

The excess of mucus, the blood pus-corpuscles, shreds of connective tissue and even ammoniacal urine with the triple phosphates, are all the immediate effects of this practically traumatic and now septic process; simply elements in the evolution of repair of a damaged structure.

This type of lithic pyonephrosis though tending toward spontaneous recovery in the young and vigorous, may under conditions of reduced health, or if it be accompanied with a tubercular cachexia, give rise to grave local changes and necessitate the intervention of surgery for its alleviation or cure. .

No doubt, the use of the endoscope or the ureteral catheter might enable us to more definitely fix the organ involved; but as a rule the clinic symptoms with uranalysis are sufficiently emphatic and positive without resorting to their employment.

Cases 9, 10 and 11.—The following three cases came under my observation during the past winter. They were females; in two malignant disease was suspected. They were seen in consultation with Drs. J. A. Hoffheimer, John Martin and Charles F. W. Horn.

In Dr. Hoffheimer's case, pyloric cancer had been suspected. The patient was a married woman 40 years old. Along with evidence of disease along the urinary tract she had pronounced symptoms of pulmonary tuberculosis. On examination, subjective and objective, with uranalysis and morphologic examination of the sediment of urine, of anatomic and bacterial elements, I felt warranted in excluding gastric cancer. The tumefaction in the epigastrium was evidently an enlarged kidney displaced inward. My diagnosis was, tubercular pyelonephrosis consecutive to pulmonary infection. Although she was of a robust physique and a full habit, when seen by me, she died within two months.

An autopsy made by Dr. Hoffheimer verified the diagnosis.

Dr. Martin's patient was an elderly woman of 57 years, rather pale and emaciated. Six months previously she lost a daughter from pulmonary phthisis. In this instance the trouble was in the left side, where a hard tumefied mass gave rise to the suspicion of cancer of the cardiac end of the stomach.

This patient too had quite unequivocal signs of pulmonary tuberculosis. Her vesical symptoms, pyuria and other features led me to locate all her abdominal symptoms as exclusively of renal origin, pyelitis, pyelonephrosis, periodic occlusion of the ureter and intrinsic cystitis. The microscopic examination of three different days' urine decided beyond question the renal origin of suppuration. This patient went steadily down, dying six weeks later. An autopsy was refused.

The third of this group was a case of *traumatic pyelonephrosis.* The patient was 61 years old and mother of a physician. She had been injured over the right kidney some five years before. From some of the symptoms present it was at first supposed that the cause of all her trouble was Bright's disease; but latterly, as her distress became particularly accentuated in the right lumbo iliac region, it was beginning to be feared that she had a new growth.

She was a large, heavy person, and though organically sound except for this lesion, she was now quite disabled from anything like active exercise.

In her case, after a surface inspection, an examination of all the symptoms and organs, with repeated uranalyses on different days and different hours of the same day, indubitable evidence of pyelonephrosis involving the right kidney was present.

The most remarkable features in connection with this case were the intermittency of the pyuria and renal intumescence on the side involved. Sometimes the urine would be highly charged with pus, epithelia and the triple phosphates and clearly ammoniac alkali; while the following day, or even later in the same day, it would clear up, reduce in specific gravity and again become strongly acid.

Then for hours, though vesical tenesmus was most distressing, but little urine came, until another spell of renal colic set in, when another generous discharge of urine followed, with transient relief.

In this case a moderate quantity of albumin was always present.

In the first and second case of the last group the interesting question rises, as to whether the tubercular abscess of the kidney was consecutive to the pulmonary lesion, or the development of the latter was simultaneous with the former.

We can readily understand how tuberculous infection may travel up a mucous membrane, as from the bladder, but we had no evidence here of an ascending infection. Authors in pathology tell us that tubercular infection may spread along the lymph current or through the blood vessels; but the lymph current moves in a centripetal direction, and if the germs are swept along the arterial tide into the renal parenchyma, how is it that the bacillary mites pass by untouched the lymphoid structures for which they have a special affinity, and fall on an epithelial organ like the kidney?

It will require very much future research to clear up this side of the question in renal tuberculosis.

It might be inquired why an operation was not pressed for in these three cases? In the presence of progressive pulmonary tuberculosis it is unwarranted. Advanced age precluded it in the third case.

DISCUSSION.

Dr. **CHARLES P. NOBLE** of Philadelphia—I would like to add my testimony to the value of direct examination as an aid to diagnosis in suppuration of the kidney. During the last two years I have seen four cases of this kind, two of which I operated on, and two were in the hands of other physicians. In these cases it was quite possible to make an absolute diagnosis by catheterizing the two ureters, finding the urine distinctly normal in one case. In one instance there was no urine secreted from one kidney; all of the urine came from the opposite kidney. The urine in one case from the affected side was full of pus. Both cases were operated on; the cause of suppuration was primary tuberculosis of the kidney. These patients made good recoveries and have done well since.

One of the most interesting cases from the standpoint of diagnosis was one which I saw recently. A diagnosis had been made of suppurating kidney, and an operation had been made to remove the kidney, with the result that the surgeon, a competent man, failed absolutely to find it and came to the conclusion that the diagnosis was erroneous, and that the woman had not a kidney on that side. I saw her later, and examination by the cystoscope and catheterization of the ureters showed that there was no question about the presence of the kidney on that side. Foul smelling urine was discharged from that side. There is no doubt whatever that the patient had a suppurating kidney, although a direct incision failed to find it. I would urge the necessity of not only making a microscopic examination of the urine, but of determining definitely, in women, where the urine comes from.

Dr. A. H. **TUTTLE** of Cambridge, Mass.—My experience with suppurating kidney is limited to one case in the past year. The case was one of long standing and a diagnosis was made simply from the situation of the tumor and by repeated emptying of the contents of the tumor into the bladder and the evacuation *of large quantities of pus. The case was allowed to go without* treatment for a year, when she came to my private hospital. At that time I began to catheterize the ureters, but there was a stricture of the ureter about one inch from the pelvis of the kidney which made it for a long time difficult to enter the kidney. After a while, I succeeded in entering the pelvis of the kidney, removing by aspiration about eight ounces of stinking pus. I left the catheter *in situ*, washing the kidney out daily with normal salt solution, and used about 2 per cent. solution of nitrate of silver. At the end of twenty one days the urine was fairly sweet; there was comparatively little sediment in it, and the catheter was removed with the hope, at that time, that the kidney would drain itself; but at the end of forty eight hours severe symptoms set in, the catheter was again intro*duced, pus withdrawn, and the kidney again cleaned.* It became impossible to keep the catheter *in situ*, and it had to be removed again. A third attempt was made to pass the catheter into the ureter, but it was impossible to do so. At this stage something had to be done on account of the bad condition of the patient. It was impossible to remove the kidney, and so an opening was made in the side, through which the kidney was washed out. The case went on and made a slow and complete recovery. The patient still retains the tube in position and by means of an elongated rubber tube she can collect all the urine during the day without soiling the clothes, and by emptying the tube at intervals of an hour or two she gets along very comfortably. If I had known as much then as I do now I should have performed a surgical operation. Her *urine has been examined from time to time*, and there is a little pyelitis in the other kidney. The amount of urea excreted from the diseased kidney is about two grams.

Dr. **MANLEY**, closing the discussion—My paper includes the subject of catheterization of the ureters, but you must remember that while the catheter has a large range of application in the female, it has but a very limited one in the *male*, particu*larly where the patient happens to have stricture*, prostatic hypertrophy, or where there is a stenotic condition of the urethral canal. You can understand a condition being present, which Dr. Noble mentioned, in which the ureter is closed by stricture, that the catheter is negative in its findings. There is more or less irritation of the bladder. The bladder in these cases is more or less inflamed and requires expert handling. The same objection applies to the cystoscope as to the urethral catheter in the male. If there be a tendency to oozing of blood, as there usually is in the turgescent stage of cystitis, the findings may be indefinite.

The object of my paper was to encourage a more systematic and methodical and practical study of the morphologic findings in the sediment of patients suffering from pyorrhea of the kidney. I *feel confident that if we examine patients carefully* and sytematically, in every instance we can *determine whether* the pus is cystic, ureteral or renal. I *refer now to the male.* You must understand that in t[illegible]male a different course must be pursued [illegible] t[illegible]ition of t[illegible]

THE TREATMENT OF PUERPERAL SEPSIS.

Presented to the Section of Obstetrics and Diseases of Women, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, June 1-4, 1897.

BY E. E. MONTGOMERY, M.D.
PHILADELPHIA, PA.

Before the Obstetric Section at Atlanta, last year, I read a paper on the "Administration of Antistreptococcic Serum," based on my experience in one patient treated the February preceding. But little had been done at that time in the treatment and study of this practice. During the year very much has been added to the literature, although its value still remains *sub judice*. The importance of the subject can not be overestimated when we appreciate not only the serious mortality, but the influence upon the subsequent health of the individual, which must result from an attack of sepsis. I do not feel that the subject of the value of the serum therapy has as yet been sufficiently demonstrated to justify the physician in trusting to it alone; in other words, every means should be exercised which will increase the vitality of the patient, and thus enable us to secure immunity against further ravages of the disease. The value of the agent seems to have been sufficiently demonstrated, however, to justify us. not only in using it, but in asserting that the physician is derelict in a case of undoubted sepsis where he does not practice its use early in the treatment. While a number of cases have been reported during the year, in which the administration of the antitoxin has had marked effect even in the late stages of the disease, and where the condition of the patient seemed absolutely hopeless, yet it certainly is not wise that we should wait until such a time before its administration. In the consideration of its use, it is also equally important that we should be able to determine or have an idea that in the administration of the serum, it is being given in cases which are suffering from a specific condition. In other words, the antistreptococcic serum has not been found so effective or valuable in those cases in which there is mixed infection, particularly the bacilli coli communes, and we can readily appreciate that when a patient is suffering from a state of sapremia or putrid intoxication, and we administer a large dose of antistreptococcic serum, we are introducing an additional poison for which the disordered system must provide. Where it is possible, it would undoubtedly be better, if it can be accomplished quickly, that a bacteriologic investigation of the secretions should be made; but as this requires time, and in some cases valuable time, and under many circumstances, unless the practitioner has proper facilities for bacteriologic investigation it would be impossible, we are obliged to depend somewhat on our judgment and the physical signs, to determine the character of the condition. The occurrence of elevation of temperature following the delivery of the patient, or an abortion, should be considered as an urgent reason for careful examination to determine its cause. This may be produced by a disordered condition of the mammary gland, by the excitement from the development of milk secretion, or may result from retention of masses within the uterus, which become putrescent and cause what is known as putrid intoxication. When the examination of a patient determines the absence of anything within the uterus which should afford a cause of high temperature, associated with profuse discharge, or possibly in the beginning an arrest of lochia, and particularly where there is redness or swelling of the vagina, exfoliation of the mucous membrane, presence of diphtheritic exudation upon, or ulcerations of its surface, the condition should be recognized as sepsis and treated accordingly by the administration of the antistreptococcic serum, together with local cleanliness and constitutionally supporting measures. The dose of the serum will depend somewhat on the virulence of the condition; thus, if the temperature is high, symptoms marked, the dose should be as high as 25 or 30 cubic centimeters of Marmorek's serum. As this serum gives immunity only for a short period, the remedy should be used the following day or earlier, if the symptoms are virulent, and continued until the abnormal symptoms subside. The literature of the last year affords a large number of cases to which refences might be made in support of this plan of treatment, but I will content myself with calling your attention to the history of the patient which I reported in my former paper, and two other cases, one of which I saw in consultation, and the others occurred in the experience of one of the assistants in my clinic.

The case previously referred to developed an attack of sepsis the third day following her labor. When seen by me there was some induration in the broad ligament on the left side. The uterus was carefully curetted, removing nothing more than the debris and some small blood clots. It was irrigated, packed with iodoform gauze, an incision then made into Douglas's pouch, and some slight amount of plastic material removed by irrigation. A gauze drain was then introduced. The whole vagina was red, swollen, and covered with a glairy mucus, which was removed by scrubbing with creolin and soap mixture prior to the operative procedure. There was a slight subsidence in the temperature the following day, but on examination over the vulva, it was found that the redness of the vagina extended upon the vulvar surfaces, producing an erysipelatous blush. This condition extended until the entire portion of the body, with the exception of the forearms and hands, and the face, became covered. At the end of three weeks, the fourth week after confinement, this erysipelatous blush had thus extended, and the patient had had more or less continuous elevation of temperature; it was then 103.3 degrees, with indications of a second extension of the erysipelatous condition. The patient had been given large doses of strychnin, stimulants, nuclein and nutritious food administered. At this time hypodermic injection of 25 cubic centimeters of antistreptococcic serum prepared in Gibier's institution was introduced. This was repeated three times with a subsidence of temperature after each injection, and the subsequent convalescence of the patient was uninterrupted, the health becoming fully restored.

The next patient was seen in consultation with Dr. Donnel Hughes of this city, who gives the following: "I send you a short history of the case of Mrs. M. who had had a temperature ranging from 103 to 105 degrees for twelve days, when at your suggestion antistreptococcic serum was given. The first day she received an injection of 25 cubic centimeters. The temperature decreased from 105 to 102 degrees; next day 12.5 cubic centimeters, temperature fell to 101 degrees; third day 12.5 and it became 99 degrees; fourth day, 12.5 and temperature became normal; subsequent convalescence was uninterrupted. Patient made a complete recovery."

Dr. Irwin writes as follows: "On Dec. 15, 1896, I was called to see a case in practice, with a midwife. The patient was 22 years of age, a primipara, who had been in labor sixteen hours; the membranes had ruptured several hours before my arrival. The head was wedged into the pelvic cavity in a left occipito-anterior position. Her pains were irregular, weak and ineffective. Ether was administered and the fetus delivered with forceps under strict antiseptic precautions. The pelvic floor sustained a deep laceration, but owing to the contused and bruised condition of the injured tissues, immediate repair was not considered advisable. Twenty-four hours later, the patient complained of rigors, followed by rapidly rising temperature, reaching 104 degrees F., with pulse 120. Her general condition daily grew worse, temperature fluctuating between 101 and 104.5 degrees, lochia very profuse, within a few days very offensive, no tympany, and slight pelvic tenderness. On the sixth day following the delivery she was seen with me by Dr. Fisher. Examination disclosed a closely adherent pseudodiphtheritic exudate covering the vaginal mucous membrane, including the cervix. The patient had general pelvic tenderness. The uterus, although large, was freely movable and the vaginal fornices and supravaginal structures pliable. The uterus was easily dilated. Its cavity measured about four and one-half inches in length, was free from clots and débris, and likewise lined with a continuation of the pseudomembrane. Under these circumstances we did not feel that curettement was indicated. The uterus was irrigated with a hot solution of bichlorid, 1 to 5000, followed by a light iodoform gauze pack of both uterus and vagina. The following twenty-four hours presented no favorable change, either locally or constitutionally. The gauze was removed, the parts irrigated with a 2 per cent. solution of creolin. The patient presented every appearance of profound septic absorption, temperature 104 degrees, pulse 140. The conditions were such as to justify us, even in the absence of a bacteriologic examination, in feeling that the infection was from streptococcus. At Dr. Fisher's suggestion, an injection of 5 cubic centimeters of Marmorek's antistreptococcic serum was used at 10 A.M., when at 2 P.M. the temperature had declined to 99 degrees, and nine hours later touched normal. The favorable condition continued until one o'clock the following day. It was six in the evening when the temperature reached 101 degrees, when a second injection of serum, the same quantity, was administered. The discharge from the vagina was still profuse, watery, very offensive, the pseudomembrane was evidently undergoing rapid disintegration and within eighteen hours it had wholly disappeared. Throughout the two succeeding days the temperature remained below 100 degrees; the patient's color, appetite and general condition were very much improved. An injection of the serum had been given each day. The fourth day the serum was omitted. The following morning the temperature of the patient again reached 104 degrees, with pulse 130, but declined to 99.5 degrees within four hours after the serum injection. Five cubic centimeters of the serum were given every alternate day for a week longer. The temperature during this time never exceeded 100 degrees, and finally became normal, which marked the beginning of a rapid convalescence. The patient, both before and during the period of the serum injection, was given stimulants and supporting measures in the form of nutritious and easily digested food, alcohol, strychnin and the antiseptic douches were administered daily. She made a perfect recovery.

While these three patients are not sufficient to enable us to assert that we have an infallible means of treatment of puerperal sepsis, yet the result in each one has been so marked after the use of the serum that they certainly justify its further consideration and employment. It is true these cases might all have recovered by other means, but I know of no plan of treatment which would have afforded the striking change in the progress of the cases as has been evident in all these cases after a practice of the serum therapy.

CLOSURE OF THE ABDOMINAL INCISION.

Presented to the Section on Obstetrics and Diseases of Women at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY PHILANDER A. HARRIS, M.D.

PATERSON, N. J.

A great deal has been said and written of late about the perfection of gynecologic operative technique least calculated to render necessary secondary operation. There is probably no condition following the gynecologic abdominal incision which calls more frequently for a secondary operation than that of hernia appearing at or in the line of the incision. It is extremely embarrassing to have our patients return exhibiting a hernia at one point or other of our incision, and still more humiliating to find that a patient goes elsewhere and receives the announcement. It is the purpose of this paper to deal briefly with what the writer esteems to be the more important points in the closure of the ordinary and median line of abdominal incision, between the umbilicus and the pubes.

Until the past few years, as we all well know, the general custom of through and through interrupted stitching prevailed everywhere. The frequency with which hernia was encountered, led to a great variety of methods of closing the wound. From that experience we have derived a technique which, although not perfect, is more calculated to obviate one of the serious drawbacks to the abdominal incision.

The gross appearance of the layers forming the abdominal wall at the line of this incision, will reveal, first, skin; then a layer of cellular tissue and fat; immediately beneath and closely adherent to this the strong fascia or conjoined tendon and aponeurosis of the oblique and transversalis muscles. This will vary in thickness from ordinary blotting paper to three or four thicknesses of the same. Then we observe the rectus muscle. Pushing this aside, or splitting it with our fingers, or the handle of a scalpel, we reach the peritoneum. It is reasonable to suppose that when we cut these structures we should on closing the wound bring the respective and corresponding parts together. Theoretically we would, therefore, first sew peritoneum to peritoneum, muscle to muscle, aponeurosis to aponeurosis, fat to fat, and skin to skin. Practically, I do not think that it is necessary nor wise to attempt as much as such theoretic considerations would indicate. I believe, however, that we should, as routine practice, sew first the peritoneum with continuous catgut, or other absorbable suture, using a modified Lembert stitch. Next, to sew with chromicized catgut, kangaroo tendon, or other absorbable suture, which *will hold for at least* one month, the opposing edges of the aponeurosis of the abdominal muscles. It has been the custom of some operators to sew this aponeurosis with a running suture. If the stitches thus made should be exceedingly closely taken, and both ends of the thread well anchored the effect secured may be both immediately and remotely satisfactory. Instead of employing a continuous suture I employ the more commonly used interrupted stitch, placing the stitches not further than one-third of an inch apart. As to the approximation of the fatty tissue, I believe there is little excuse for sewing it, excepting where the layer of fat is unusually thick. I believe that this fatty tissue is sufficiently approximated with the addition of the skin suture. Except for esthetic reasons, I do not think that it matters very much what sort of stitch we employ for the skin. The cutaneous sewing which I have used for about three years, to the exclusion of almost all other forms, is the so-called subcutaneous suture, often referred to as the Halsted or Marcy stitch. I do not know which of these gentlemen was the first to use this particular stitch in surgery, but I do know that it effects a beautiful result. I have employed both catgut and silk for this subcutaneous suture, but prefer the latter, for it need not be afterward removed. The employment of silver wire, or silk, for the subcutaneous suture necessitates a good deal of pain oftentimes to effect its removal. To assure a patient who has experienced more or less anxiety and horror in connection with her operation, that there are no stitches to be removed during her convalescence, gains for us both her esteem and gratitude. The incision closed in this manner effects, I believe, the best possible results for both practical and esthetic reasons.

Regarding the employment of non-absorbable buried sutures, a number of good operators, realizing the importance of this system of tier suturing the abdominal incision, and having felt hitherto an unwillingness to trust to the sterilization of catgut, or fearing its absorption before its work is completed, have esorted to silk suturing of the peritoneum. For imilar reasons they have also employed very extensively buried silver wire and silkworm gut suture in the severed aponeurosis. I employed for about two years, and until recently, silkworm gut for the aponeurosis, tying three knots and cutting the ends closely on the last knot with the scissors. A very small percentage of these cases suppurated and required a withdrawal of one or more of the sutures. In two cases I experienced a great deal of embarrassment in finding the offending ones. I believe that by discontinuing the employment of non-absorbable sutures in the aponeurosis and the use of kangaroo tendon or chromicized catgut the few embarrassments I have had in this relation will immediately lessen. My feelings, indeed, regarding the employment of non-absorbable sutures of any sort whatever, is so strong that I can hardly now realize that I shall ever again employ them. Possibly others have been more fortunate in this relation than myself.

Regarding the *strength* of the abdominal wall at point of incision, when united by the non-absorbent tier suture, I am convinced that it is far greater than that attained by the through and through, semi-through and through, or any other modification of sewing which I have practiced or studied. If these results have been attained by the non-absorbent suture in the aponeurosis, I am forced to believe that nearly, if not quite, as satisfactory work, may be accomplished with the slowly absorbable kangaroo tendon and possibly with the thoroughly chromicized catgut.

Regarding the danger of sepsis from the employment of kangaroo tendon or catgut, I may say that with the improved methods of sterilization we have very little to fear.

As to the particular structures which contribute to the tensile strength of the abdominal wall at this point for lateral strain, much might be said, but as to the tissue which furnishes the major tensile strength for such strains, I do not see how any one can attribute very much to any of the tissues excepting the aponeurotic terminations of the oblique and transversalis muscles. To such operators as have had no experience with suturing of this aponeurosis, I would say, that, excepting for theoretic and more or less uncertain clinical reasons, they should have little cause for contradicting these assertions. From an anatomic standpoint, they should concede the claim which is made, that this particular tissue furnishes the major part of all the tensile strength for lateral, and to a very considerable degree, vertical strains. Peritoneum holds little; the rectus muscle should hold only one way, namely, in vertical strain; cellular and fatty tissues hold very little; skin holds nothing; it only covers; so that, of these various structures, we must look chiefly to the aponeurosis of the abdominal muscles for tensile strength. Therefore, whenever we cut this aponeurosis or fascia, we should properly coapt its edges; if we do not bring them well together, we are allowing a less resistant structure to fill the interspace and afford an opening through which hernia may occur.

I am quite aware that I have offered you practically nothing which is new in this paper; these suggestions do not address themselves to many operators who are doing good tier work. They rather seek to crystallize the good work which many are doing. I have been prompted to write on the subject from the fact that many operators remain contented with the old-fashioned through and through suture which, I believe, has been very greatly improved upon.

THE CURE OF VESICO-VAGINAL FISTULA BY THE FREE DISSECTION OF THE BLADDER FROM ITS VAGINAL ATTACHMENTS AND CLOSURE WITH THE BURIED CONTINUOUS TENDON SUTURE.

Presented in the Section on Obstetrics and Diseases of Women, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1–4, 1897.

BY HENRY O. MARCY, A.M., M.D., LL.D.
BOSTON, MASS.

In 1887 my attention was first called to the ease with which the bladder wall will reunite after injury, under the most adverse circumstances, when the portion involved is free within the peritoneal cavity. The case upon which I operated at this time was that of a child eighteen months old, where an abscess in the vicinity of the appendix had resulted in a vesico-intestinal fistulous opening in the appendiceal region.

Laparotomy disclosed two fistulæ of the small intestine, complicated with an opening into the bladder to the right of the fundus. The intestines were freed from adhesions and drawn out of the wound. The refreshed edges of the openings were closed by double lines of fine continuous tendon sutures, which in turn were intrafolded by a second layer of continuous tendon Lembert sutures. After the intestine had been returned, the bladder wall was freed from its adhesions, the opening into it refreshed and sutured in double lines of continuous tendon sutures, in precisely the same manner as I had closed the intestinal wounds.

The child made an easy and perfect recovery, with primary union of the openings, and is today a strong, vigorous girl. The age of the child rendered drainage of the bladder unsuccessful, but from the first the function of the organ seemed little impaired.

The case was instructive in many ways. Perhaps the most important lesson was the primary restoration of the bladder wall without the supposed necessary physiologic rest of the organ. The method of applying the first row of sutures in the approximation of the refreshed edges, held in even support by means of the continuous sutures, inverted the mucous membrane.

The insertion of the suture in both intestinal and bladder walls is in the following manner: The needle is a fine one, curved upon the flat, with eye near the point, and set in a firm handle, made to penetrate the coats of the bladder or the intestine also, but not through the mucous membrane. It emerges about one-quarter of an inch from the line of the opening, and is introduced upon the opposite side at a like distance. The needle is then unthreaded, rethreaded with the opposite end of the suture and withdrawn. This makes the needle a suture carrier like a shuttle, and holds in even coaptation the included structures in a double loop from side to side (shoemaker's stitch). One stitch follows another in an even continuous seam, until the opening is completely closed. By this side to side coaptation, the parts enclosed are held in juxtaposition the *breadth* of the enclosing loop, while the interrupted suture holds only the *width* of the suture material. The submucous penetration of the needle buries the suture in healthy vitalized structures and the line of stitches, taken a quarter of an inch away from the edges of the wound, inverts the mucous membrane into the bladder. The final fixation of the suture is by one knot, a manifest advantage over leaving as many knots as stitches, while the continuous suture permits of an even adjustment of the enclosing force. It must be remembered that no undue force is used in the tightening of the stitches, since readjustment, retention and rest with a minimum of devitalization, are the factors in the relation of the sutured parts as important as in the treatment of a fractured bone.

The exterior line of continuous Lembert sutures intrafolds the peritoneum so as to re-enforce and greatly strengthen the structures over the wound. When taken properly they are themselves buried without puckering of the peritoneum (parallel continuous suture).

From a variety of causes, quite a number of times within the last ten years, I have closed wounds in the bladder from within the peritoneal cavity as above outlined, and in every instance primary restoration has occurred. But in the entire series I have been enabled to drain the bladder for a number of days through the urethra.

During this period, in the larger number of cases of vesico-vaginal fistula, I have closed the wound through the vaginal opening by lines of buried tendon sutures, with varying results. Little by little I have found that both ease of operation and certitude of outcome seemed dependent on the freedom of dissection and the amount of tissue held in fixation. Especially has it appeared dependent, in considerable degree, on the extent of the dissection of the bladder from its vaginal attachments. Then the importance of the lesson taught me by the safe repair of the bladder wounds from within the abdominal cavity became apparent. From this standpoint I reviewed with renewed interest the entire history of surgical operations undertaken for the cure of vesico-vaginal fistula, from the days of Sims and Bozemann in this country and Jobert and Simon of Europe.

The various modifications in technic and detail of these great masters, save the introduction of antiseptic measures, has been that, little by little, without the recognition of the underlying anatomic reason, the successful cure of large vaginal fistulæ has been dependent on the greater freedom of dissection by which, the bladder has been separated from its vaginal attachments.

I can not myself question that the primary cause of failure, the surgical technic having been satisfactory, lies in the anatomic conditions, the importance of which, a study of the physiologic functions of these different organs makes easily apparent. The contraction of the circular fibers of the vaginal muscle tends constantly to pull upon the base of the bladder, and these muscular contractions are necessarily called into special activity following the irritation incident to the repair of a vesico-vaginal fistula. When both the bladder wall and the vaginal muscle are united by sutures, holding them in approximation, the contraction of the vaginal muscle not alone pulls upon the suture, causing it to cut through its own structure, but at the same time acts with equally destructive force upon the enclosed bladder wall. I believe that it is on this account that the great majority of failures to cure vesico-vaginal fistulæ ensue.

Reflection on the diverse physiologic relationship of the parts involved must lead to the conclusion that, at least, this is an hitherto overlooked important factor for surgical consideration, and I now invite the profession to give it due consideration in order to profit, as far as possible, from its better understanding, by the adaptation of improved surgical methods.

Every one who is familiar with anterior colporrhaphy for cystocele knows the comparative ease and safety with which a large portion of the vaginal muscle may be dissected from the dependent posterior bladder wall, and the almost sure complete primary union which ensues upon its fixation and closure.

It is safe, and not very difficult, having split the edges of a refreshed vesico-vaginal fistula, to separate widely the bladder from the vagina. When this has been effected, but not until the dissection is complete, the opening in the bladder wall is refreshed and closed by a double line of continuous sutures, as already described, carefully avoiding penetration of the mucous membrane, using for suture material a fine tendon.

By the use of a needle with the eye near the point, the suture is carried back and forth through the same stitch opening, precisely as the shoemaker sews leather.

The opening in the viscus is then closed by an even, uniform support, coaptating but not unduly compressing the enclosed structures A single knot fixes the suture, a fact of considerable importance when the material used is to be left buried. The free dissection makes the union of the bladder wall a comparatively easy operation, and even when a large portion of the vaginal vault has been lost, there is little difficulty in effecting an easy uniform closure without tension of the bladder wall. As every operator knows, in large fistulæ, when the vaginal structures are enclosed with the bladder wall, this part of the operation is exceedingly difficult, and the tension upon the parts which follows is the usual cause of failure.

Therefore, again I emphasize the necessity of free dissection which, to the timid operator, at the outset seems at least to border on the verge of rashness.

The bladder wall having been closed, we have remaining an operation not unlike that ordinarily undertaken for the cure of cystocele, with the exception that oftentimes the remaining vaginal structures are unduly minimized. How these structures shall be closed, so far as the cure of the fistula is concerned, is comparatively of minor importance. It is wise, however, to restore them as nearly as possible to their primal condition. I think that this is best effected in a general way, a method which for many years I have continuously practiced, by the use of a single tendon suture applied with an Hagedorn needle, using a lacing stitch, the sutures being deeply imbedded from side to side. In this way the vaginal wall is coaptated in two or three layers and the mucous surfaces of the vagina are carefully approximated. This results in an entirely closed wound, the antero-posterior diameter of which has been considerably increased; in the first place, by the inversion of the mucous membrane of the bladder; in the second place, the approximation of the widely denuded structures upon the median line; and in the third place, by the inversion of the approximated vaginal surfaces of the wound.

Fistula in which the cervical portion of the uterus is involved comes easily under the same general plan of operative measures. The organ must be freely separated from its attachments.

Recto-vaginal fistulæ are operated upon by essentially the same method. From below through the perineum the vagina is freely separated from the bowel. The opening in each is closed precisely as the opening in the bladder wall; then the perineum is restored by layers of buried tendon sutures. I have long practiced this method almost without failure, a description of which in careful detail published years ago.

Suprapubic cystotomy in the male furnishes its corroborative testimony of importance in this direction. Here a large wound of the bladder is made with *seeming impunity* for a variety of reasons, the bladder wall independently closed, the superadjacent structures united in layers, the skin rejoined by a buried suture and the wound sealed without drainage. The suprapubic attachment of the bladder is by loose elastic structures which furnish the conditions favorable for easy retention at rest of the rejoined bladder wall. This is the factor usually wanting in vesico-vaginal fistula, and it is on this account that the wide dissection which I have before advocated is advised. I advocated this method of operation in a paper published in 1893.[1]

Dittel,[2] apparently without the recognition of the conditions which I have emphasized, in 1893 attempted a new operation for the closure of vesico-vaginal fistula, based probably on the experiences in suprapubic cystotomy. He opened the abdomen, freed the uterus and the vagina, sutured the fistula and then closed the peritoneal incision through the vesico-uterine space. This operation has its merit, in that it accomplishes the purpose above outlined. If for any other reason a laparotomy is necessary this method of closure of the vesico-vaginal fistula might be adopted, but hardly otherwise.

Mackenrodt of Berlin, in 1894, advocated a free dissection not unlike that which I have above described, after which he united the wound in the bladder with fine silkworm gut sutures. Then he closed the vaginal wound by drawing the body of the uterus forward so as to give the parts as far as possible a support from this organ.

Schauta[3] in adherent vesico-vaginal fistula advises a vertical incision, lateral to the left labium majus, dissecting down to the descending ramus of the pubes. Separation of the cicatricial tissue, walls of the vagina and fistula from the bowel by means of a periosteal elevation as far as the obturator foramen.

Ferguson[4] advocates the following method of closure: The fistulous opening being exposed, an incision is made through the mucosa of the vagina at the distance of a full eighth of an inch from the opening of the margin of the fistula. This incision is extended until it completely encircles the opening. The line of the incision is carefully deepened until the lining membrane of the bladder is reached, and great caution is exercised in retaining the integrity of that membrane. In this manner a circumfrontal flap, hinged by the mucosa of the bladder, is obtained. This flap is inverted into the bladder and held in position by a continuous catgut suture. There is no loss of tissue and a very broad raw surface is obtained for apposition.

Walcher advocated cutting away all tissue and, without making it quite apparent as to the purpose, he evidently frees the bladder freely from its vaginal attachments and unites the bladder wound with catgut sutures taken one-fourth of an inch from the edge of the fistula. After these have all been inserted they are tied. The bladder having been thus closed, the vaginal flaps are united by a line of silk sutures.

Howard A. Kelly, M.D. of Baltimore, has made a valuable contribution on this subject,[5] in which he reverses in large measure this very process, by dissecting the bladder, from behind forward, from its uterine attachments quite beneath the reflected peritoneal fold, and in this way is enabled to draw the posterior wall of the bladder downward by a layer of fine interrupted silkworm gut sutures, taken inferiorly through the bladder wall and its vaginal attachment. In the illustrated case, Dr. Kelly thought this measure advisable, because of the relation which the ureteral openings had to the bladder wound. The result seems to have justified the novel measure employed, and yet I am very sure the conditions will be rarely found which render this method of procedure advised. We are deeply indebted to Dr. Kelly for bringing to the attention of American surgeons and emphasizing the importance of the catheterization of the ureters prior to operation upon large vesico-vaginal fistulæ.

He claims for his method the advantage, in that the ureters are not involved, that he does not in any case include the uterus as a factor of repair, and that his method is easier to apply where the destruction of the tissue is so great as to include the upper part of the urethra. This I believe to be important, but it does not seem to me that the union of the posterior bladder wall with the anterior vaginal wall is ever to be advised when lateral approximation upon the median line can be effected.

The advantages I claim for my method are apparent. It is based: 1, on the anatomic and physiologic relationship of the approximated organs; 2, on the comparative ease of operation made possible by a free dissection; 3, the far greater probability of cure of large vesico-vaginal fistulæ, where a considerable portion of the vaginal tract has been lost; 4, the great advantage obtained from the lateral approximation of the structures on the median line; 5, by the use of aseptically buried tendon sutures the parts are held at rest in easy apposition and primary union follows, with no subsequent care of the wound and no removal of sutures.

THE NECESSITY OF FIXED CRITERIA IN THE STUDY OF THE THERAPEUTICS OF TUBERCULOSIS.

Presented to the Section on State Medicine at the Forty-eighth Annual Meeting of the American Medical Association, at Philadelphia, Pa., June 1-4, 1897.

BY LOUIS FAUGÈRES BISHOP, A.M., M.D.
CHAIRMAN SECTION ON GENERAL MEDICINE, NEW YORK ACADEMY OF MEDICINE; SECRETARY SECTION ON STATE MEDICINE, AMERICAN MEDICAL ASSOCIATION; MEMBER NEUROLOG. SOCIETY, ETC.
NEW YORK.

There is nothing more trying in the search after truth in therapeutics than the absence of fixed criteria. Much as this is felt in every department of medicine, in the field of tuberculosis it becomes fairly disheartening. The therapeutics of tuberculosis has been so widely extended with really so few points at which it has been advanced, that we need above all things at the present time to study it in general, apart from its application to single cases. In other departments of human knowledge there are works that take up a subject itself apart from its relations. There is a grammar of grammars. There is a chemic philosophy. There are books on pure mathematics. Some one is needed who, abstracting himself from the advocacy of any particular method, will lay down a standard to which all methods can be brought for measurement. It is not intended at the present time to attempt a definite plan, but rather to suggest its necessity so that various men may take it up and finally the desired result may be accomplished. This advance would not be unparalleled even in the history of tuberculosis. In the field of diagnosis we have reached certain ground by our knowledge of the bacillus discovered by Koch.

There is need in the first place of a definite plan of classification of cases. The old division into stages has proved unsatisfactory. The problem is a more complicated one than that. The classification must include more elements, such as heredity, race, temperament, condition of life, mode of infection, exact location and extent of the lesion. Then there might be included various personal equations, such as may be eventually evolved from the physiologic laboratory. By giving its true value to each element an equation might be reached that would express the therapeutic weight of the result should improvement follow in any particular case.

The advance in knowledge due to the discovery of the tubercle bacillus has blinded us to the fact that there are still a great many things that we do not know. It is evident that the process of cure of tuberculosis is different from that of many other infectious diseases, such as diphtheria. In other infectious diseases the bacilli seem to perish, each on account of the product of their own living, while the tubercle bacillus seems to prepare the soil for the future growth of its kind. Again, the large number of people who are much of the time immune to the infection of tuberculosis, and yet who may any moment give a harbor to this germ, makes it evident that there is some peculiar and probably physiologic barrier that has given way at the critical moment. If this condition, which for the want of better knowledge, we call immunity, could be better understood in the case of tuberculosis, as its parallel condition has been worked out in diphtheria and the other diseases for which we can vaccinate, the problem of the prevention and treatment of tuberculosis would be a much simpler one. It would seem that a new principle must be discovered somewhat different from the principle upon which antitoxin is able to work, and it is just possible that some undiscovered chemic germicide will be the agent. Looking over the community at large if we had means of analysis, we would find that there are people suffering from tuberculosis, susceptible people and immune people. When we are called upon to treat a case of beginning consumption we cast about for means of restoring that person to his previous existing state of immunity. This we do by more or less general constitutional measures. It is not altogether a common, and yet a frequent observation, that among the poorly cared for classes there are cases in which there has been a fairly large amount of destruction of lung tissue who recover spontaneously even under the most adverse conditions. If we could investigate these cases with their surroundings it might be possible to discover some uniform condition as a basis for study, just as the immunity from smallpox, of those who cared for cows who had a certain disease, led Jenner to the investigation which enabled him to save as many lives as would be saved by a cure for tuberculosis.

In order to bring in review the different plans of treatment of tuberculosis as carried out in various parts of the world we should have a court before which the claims of each might be reviewed. It can truly be said that there is no great superiority of any particular method. We may look with hope in the direction taken by laboratory and physiologic experiments that have led to results in the case of other diseases. On the other hand, impartial clinical observation of the natural course of untreated cases, or of cases in which it has seemed certain that the drugs used were without effect, often leads to a state of mind which accepts with scepticism the results of any specific plan of treatment.

In New York City the climate is notoriously bad for lung diseases, and yet now and then a case with advanced lesions, while under the writer's observation, has shown great improvement and come to a standstill when practically no medicine was used at all, the improvement being apparently due solely to a more hygienic mode of life, or perhaps the leaving off of the excessive use of alcohol. It is needless to remark suture, a fact of considerable importance when the material used is to be left buried. The free dissection makes the union of the bladder wall a comparatively easy operation, and even when a large portion of the vaginal vault has been lost, there is little difficulty in effecting an easy uniform closure without tension of the bladder wall. As every operator knows, in large fistulæ, when the vaginal structures are enclosed with the bladder wall, this part of the operation is exceedingly difficult, and the tension upon the parts which follows is the usual cause of failure.

Therefore, again I emphasize the necessity of free dissection which, to the timid operator, at the outset seems at least to border on the verge of rashness.

The bladder wall having been closed, we have remaining an operation not unlike that ordinarily undertaken for the cure of cystocele, with the exception that oftentimes the remaining vaginal structures are unduly minimized. How these structures shall be closed, so far as the cure of the fistula is concerned, is comparatively of minor importance. It is wise, however, to restore them as nearly as possible to their primal condition. I think that this is best effected in a general way, a method which for many years I have continuously practiced, by the use of a single tendon suture applied with an Hagedorn needle, using a lacing stitch, the sutures being deeply imbedded from side to side. In this way the vaginal wall is coaptated in two or three layers and the mucous surfaces of the vagina are carefully approximated. This results in an entirely closed wound, the antero-posterior diameter of which has been considerably increased; in the first place, by the inversion of the mucous membrane of the bladder; in the second place, the approximation of the widely denuded structures upon the median line; and in the third place, by the inversion of the approximated vaginal surfaces of the wound.

Fistula in which the cervical portion of the uterus is involved comes easily under the same general plan of operative measures. The organ must be freely separated from its attachments.

Recto-vaginal fistulæ are operated upon by essentially the same method. From below through the perineum the vagina is freely separated from the bowel. The opening in each is closed precisely as the opening in the bladder wall; then the perineum is restored by layers of buried tendon sutures. I have long practiced this method almost without failure, a description of which in careful detail published years ago.

Suprapubic cystotomy in the male furnishes its corroborative testimony of importance in this direction. Here a large wound of the bladder is made with seeming impunity for a variety of reasons, the bladder wall independently closed, the superadjacent structures united in layers, the skin rejoined by a buried suture and the wound sealed without drainage. The suprapubic attachment of the bladder is by loose elastic structures which furnish the conditions favorable for easy retention at rest of the rejoined bladder wall. This is the factor usually wanting in vesico-vaginal fistula, and it is on this account that the wide dissection which I have before advocated is advised. I advocated this method of operation in a paper published in 1893.[1]

Dittel,[2] apparently without the recognition of the conditions which I have emphasized, in 1893 attempted a new operation for the closure of vesico-vaginal fistula, based probably on the experiences in suprapubic cystotomy. He opened the abdomen, freed the uterus and the vagina, sutured the fistula and then closed the peritoneal incision through the vesico-uterine space. This operation has its merit, in that it accomplishes the purpose above outlined. If for any other reason a laparotomy is necessary this method of closure of the vesico-vaginal fistula might be adopted, but hardly otherwise.

Mackenrodt of Berlin, in 1894, advocated a free dissection not unlike that which I have above described, after which he united the wound in the bladder with fine silkworm gut sutures. Then he closed the vaginal wound by drawing the body of the uterus forward so as to give the parts as far as possible a support from this organ.

Schauta[3] in adherent vesico-vaginal fistula advises a vertical incision, lateral to the left labium majus, dissecting down to the descending ramus of the pubes. Separation of the cicatricial tissue, walls of the vagina and fistula from the bowel by means of a periosteal elevation as far as the obturator foramen.

Ferguson[4] advocates the following method of closure: The fistulous opening being exposed, an incision is made through the mucosa of the vagina at the distance of a full eighth of an inch from the opening of the margin of the fistula. This incision is extended until it completely encircles the opening. The line of the incision is carefully deepened until the lining membrane of the bladder is reached, and great caution is exercised in retaining the integrity of that membrane. In this manner a circumfrontal flap, hinged by the mucosa of the bladder, is obtained. This flap is inverted into the bladder and held in position by a continuous catgut suture. There is no loss of tissue and a very broad raw surface is obtained for apposition.

Walcher advocated cutting away all tissue and, without making it quite apparent as to the purpose, he evidently frees the bladder freely from its vaginal attachments and unites the bladder wound with catgut sutures taken one-fourth of an inch from the edge of the fistula. After these have all been inserted they are tied. The bladder having been thus closed, the vaginal flaps are united by a line of silk sutures.

Howard A. Kelly, M.D. of Baltimore, has made a valuable contribution on this subject,[5] in which he reverses in large measure this very process, by dissecting the bladder, from behind forward, from its uterine attachments quite beneath the reflected peritoneal fold, and in this way is enabled to draw the posterior wall of the bladder downward by a layer of fine interrupted silkworm gut sutures, taken inferiorly through the bladder wall and its vaginal attachment. In the illustrated case, Dr. Kelly thought this measure advisable, because of the relation which the ureteral openings had to the bladder wound. The result seems to have justified the novel measure employed, and yet I am very sure the conditions will be rarely found which render this method of procedure advised. We are deeply indebted to Dr. Kelly for bringing to the attention of American surgeons and emphasizing the importance of the catheterization of the ureters prior to operation upon large vesico-vaginal fistulæ.

He claims for his method the advantage, in that the ureters are not involved, that he does not in any case include the uterus as a factor of repair, and that his method is easier to apply where the destruction of the tissue is so great as to include the upper part of the urethra. This I believe to be important, but it does not seem to me that the union of the posterior bladder wall with the anterior vaginal wall is ever to be advised when lateral approximation upon the median line can be effected.

The advantages I claim for my method are apparent. It is based: 1, on the anatomic and physiologic relationship of the approximated organs; 2, on the comparative ease of operation made possible by a free dissection; 3, the far greater probability of cure of large vesico-vaginal fistulæ, where a considerable portion of the vaginal tract has been lost; 4, the great advantage obtained from the lateral approximation of the structures on the median line; 5, by the use of aseptically buried tendon sutures the parts are held at rest in easy apposition and primary union follows, with no subsequent care of the wound and no removal of sutures.

THE NECESSITY OF FIXED CRITERIA IN THE STUDY OF THE THERAPEUTICS OF TUBERCULOSIS.

Presented to the Section on State Medicine at the Forty-eighth Annual Meeting of the American Medical Association, at Philadelphia, Pa., June 1-4, 1897.

BY LOUIS FAUGÈRES BISHOP, A.M., M.D.
CHAIRMAN SECTION ON GENERAL MEDICINE, NEW YORK ACADEMY OF MEDICINE; SECRETARY SECTION ON STATE MEDICINE, AMERICAN MEDICAL ASSOCIATION; MEMBER NEUROLOG. SOCIETY, ETC.
NEW YORK.

There is nothing more trying in the search after truth in therapeutics than the absence of fixed criteria. Much as this is felt in every department of medicine, in the field of tuberculosis it becomes fairly disheartening. The therapeutics of tuberculosis has been so widely extended with really so few points at which it has been advanced, that we need above all things at the present time to study it in general, apart from its application to single cases. In other departments of human knowledge there are works that take up a subject itself apart from its relations. There is a grammar of grammars. There is a chemic philosophy. There are books on pure mathematics. Some one is needed who, abstracting himself from the advocacy of any particular method, will lay down a standard to which all methods can be brought for measurement. It is not intended at the present time to attempt a definite plan, but rather to suggest its necessity so that various men may take it up and finally the desired result may be accomplished. This advance would not be unparalleled even in the history of tuberculosis. In the field of diagnosis we have reached certain ground by our knowledge of the bacillus discovered by Koch.

There is need in the first place of a definite plan of classification of cases. The old division into stages has proved unsatisfactory. The problem is a more complicated one than that. The classification must include more elements, such as heredity, race, temperament, condition of life, mode of infection, exact location and extent of the lesion. Then there might be included various personal equations, such as may be eventually evolved from the physiologic laboratory. By giving its true value to each element an equation might be reached that would express the therapeutic weight of the result should improvement follow in any particular case.

The advance in knowledge due to the discovery of the tubercle bacillus has blinded us to the fact that there are still a great many things that we do not know. It is evident that the process of cure of tuberculosis is different from that of many other infectious diseases, such as diphtheria. In other infectious diseases the bacilli seem to perish, each on account of the product of their own living, while the tubercle bacillus seems to prepare the soil for the future growth of its kind. Again, the large number of people who are much of the time immune to the infection of tuberculosis, and yet who may any moment give a harbor to this germ, makes it evident that there is some peculiar and probably physiologic barrier that has given way at the critical moment. If this condition, which for the want of better knowledge, we call immunity, could be better understood in the case of tuberculosis, as its parallel condition has been worked out in diphtheria and the other diseases for which we can vaccinate, the problem of the prevention and treatment of tuberculosis would be a much simpler one. It would seem that a new principle must be discovered somewhat different from the principle upon which antitoxin is able to work, and it is just possible that some undiscovered chemic germicide will be the agent. Looking over the community at large if we had means of analysis, we would find that there are people suffering from tuberculosis, susceptible people and immune people. When we are called upon to treat a case of beginning consumption we cast about for means of restoring that person to his previous existing state of immunity. This we do by more or less general constitutional measures. It is not altogether a common, and yet a frequent observation, that among the poorly cared for classes there are cases in which there has been a fairly large amount of destruction of lung tissue who recover spontaneously even under the most adverse conditions. If we could investigate these cases with their surroundings it might be possible to discover some uniform condition as a basis for study, just as the immunity from smallpox, of those who cared for cows who had a certain disease, led Jenner to the investigation which enabled him to save as many lives as would be saved by a cure for tuberculosis.

In order to bring in review the different plans of treatment of tuberculosis as carried out in various parts of the world we should have a court before which the claims of each might be reviewed. It can truly be said that there is no great superiority of any particular method. We may look with hope in the direction taken by laboratory and physiologic experiments that have led to results in the case of other diseases. On the other hand, impartial clinical observation of the natural course of untreated cases, or of cases in which it has seemed certain that the drugs used were without effect, often leads to a state of mind which accepts with scepticism the results of any specific plan of treatment.

In New York City the climate is notoriously bad for lung diseases, and yet now and then a case with advanced lesions, while under the writer's observation, has shown great improvement and come to a standstill when practically no medicine was used at all, the improvement being apparently due solely to a more hygienic mode of life, or perhaps the leaving off of the excessive use of alcohol. It is needless to remark that other cases have resisted every known mode of treatment, and have gone steadily from bad to worse. The crops of new treatments for consumption are about as regular as the recurrence of the months. Of these treatments one or two attain prominence and notoriety every year. The most salient fact seems to be the absolute unreliability of the testimony of patients themselves, and the impossibility for any observer to judge impartially a plan of treatment that has been the birth of his own brain. In a quiet and unbiased discussion in the Medical Section of the New York Academy of Medicine, the conclusion seemed to be that at the present time we must depend still upon the adaptation of various modes of improving the systemic forces. It would be well if there were some constituted authority in the possession of sufficient clinical material to make impartial comparisons of methods as they are brought to the notice of the profession. It is unscientific, inhuman and altogether disgraceful to the profession of medicine that every year some treatment should be forced upon the world through mere notoriety. We have recently had an instance in New York City of a so-called specific for consumption so successfully thrust upon the public of the United States, that many physicians themselves, throughout the country, have been led to look upon it as something worthy of their adoption. Strangely enough this could take place while the remedy and its author were repudiated by the profession in New York City. It should be, and probably is, a fairly simple matter for those in charge of large consumptive colonies to determine almost immediately the falsity of the claims of any such remedy as a specific. The greater the claims the easier it should be to disprove them. Some one wishing to benefit the race for all time should endow a large colony for consumptives in some salubrious climate where parallel tests could be carried on with a number of patients sufficient to eliminate the large personal element, and to bring into use the mathematic theory of chances. It is a curious fact that where money interests are involved the application of mathematics to determine the death rate under various conditions has been carried to extreme perfection, but when life without money is involved it is still very inexactly applied. The life insurance companies only insure healthy persons, and up to the present time have not attempted to estimate the chances of diseased persons under various conditions. Should it become the custom to insure the lives of consumptives, it would not be long before the same sort of discrimination would be brought to bear to determine the validity of the claims of the many treatments that are in use in various parts of the world.

We wish to make a plea for the establishment or the adaptation of some institution as a court to which each discoverer may present his cure for impartial judgement. Great is the credit of men who devote their fortunes to the cure of the sick of each generation, but much greater honor will be due to those who help, like Jenner and Koch, to discover principles that will influence for good the health of the race throughout all coming generations.

Gloves in Surgical Operations.—Wölfler uses the ordinary leather military glove, keeping it in 3 per cent. carbolized glycerin. He advises them for all septic and aseptic operations and the examination of the rectum, vagina and mouth.—*Cbl. f. Chir.*, October 9.

HEATING APPARATUS AND HYGIENE.

BY THOMAS J. JACKSON, A.M., M.D.
CLINICAL INSTRUCTOR IN NERVOUS DISEASES, COLLEGE OF PHYSICIANS AND SURGEONS.
CHICAGO.

In the interest of hygiene and good sanitation it would seem that something ought to be said concerning the increasingly prevalent use of gas and oil heaters. Particularly so, since, as ordinarily used, these heaters are not provided with a flue or any means of escape for the noxious and toxic gases they emit. They are brought into requisition mostly during that cheerless period of spring before winter has fairly left us and before warm weather is a settled certainty. So often in our capricious climate an almost torrid March or April is followed by a frigid May or June. Then it is that most families domiciled in our modern houses with their steam radiators and hot air arrangements, after the "furnace has gone out for the spring," suffer a positive hardship. How comfortable would then be the old wood or coal stove which, although possibly not so elegant, was a more efficient ventilator.

It is during this cold damp weather, in the absence of adequate heating facilities, that we have such a crop of sore throats, coughs, colds and bronchitis. The physician called to the modern house looks in vain for the means to provide his ideal warm moist atmosphere that is such a desideratum in the satisfactory management of the maladies named. He goes into the sick-room where is lying a child sick with acute bronchitis. He advises the anxious mother that some arrangement for heating the apartment must be made. She is likely to say "Oh yes, doctor, we will have our little gas stove set up at once. That is just the thing. That is what we always use to take off the chill on these cold damp days."

These heaters as used are a menace to the health of those who are well, to say nothing of their use to warm the sick-room. Especially will they be harmful in the apartments of those ill of diseases of the respiratory tract. But they are widely employed, not only by the laity but also by physicians. Their necessarily deleterious effects will readily appear to any one who will apply a few of the principles of elementary chemistry.

Let us consider the chemistry involved. Coal gas, after it is rid of its impurities, has for its approximate composition, hydrogen, carbon monoxid, methane and several hydrocarbons having the general formula $C_n H_{2n}$. When these products are burned at the orifices of the stove, it is plain that their oxidation will produce an immense volume of carbon dioxid to be thrown into the air. The quantity of this carbon dioxid will be in direct proportion to the amount of combustion, that is to the size of the fire and the heat desired. On the other hand, this combustion, this oxidation, will require a volume of atmospheric oxygen in direct proportion to the heat produced.

Now, most educated laymen know all these things, and of course all physicians do. It is not that we lack scientific knowledge, but that we do not often enough apply our science to our common every-day needs and to the solution of every-day problems.

The danger accruing from these heaters is not necessarily in their consumption of oxygen and vitiation of the air with carbon dioxid, but in the fact that, as ordinarily used, they are provided with no arrangement for the elimination of noxious gases. With the ordinary stove, there is constantly passing up the chimney a column of heated gas that leaves a partial vacuum behind it. This brings in as constantly from without a volume of atmospheric oxygen to take its place. But in the case of the heater, with no egress of carbon dioxid there is no room provided for ingress of fresh oxygen, hence no ventilation. Applying the two-volume law, it is evident that every double volume of oxygen gas will produce, after combustion of the carbon, two volumes of carbon dioxid. At a considerable rate of combustion, with no provision for exit and supply of oxygen, it will not require a very long time to transform all the oxygen available for breathing into the poisonous carbon dioxid. It may be urged that there is ingress and egress by doors and windows, but it is readily seen that this is only accidental and neither systematic nor adequate ventilation. If doors and windows were the only ventilation for a gas heater they would have to be so wide open that the low temperature of the large quantity of air necessary to provide ventilation proportionate to the carbon dioxid produced, would easily neutralize all the heat produced by the stove.

The gas fireplace usually has an ample flue and is not objectionable; nor is the gas cooking range, when fitted with a capacious hood for the conduction of fumes.

It may be said that if gas stoves are noxious, then gas jets for lighting are noxious also; and this is true. The damage is the same in kind and differs only in degree. But practically ordinary ventilation is sufficient to provide for the comparatively small amount of noxious gas produced.

What has been said of gas heaters applies equally to oil heaters. The only difference is that in this case, instead of the gaseous the liquid hydrocarbons are used, these being volatilized by heat after being carried up the wick by capillarity. Similarly what was said of gas jets as to proportionate damage, applies to oil lamps for lighting. In passing, here is an argument for the electric light.

The principles above stated apply also as against gasolin cooking stoves, but in extenuation it may be said that gasolin stoves are used in summer as a rule, when it is possible and usual, on account of the heat of the season, to have doors and windows wide open, so that ample interchange of air is secured.

The needs of the human body in oxygen are identical with those of the stove, and its product of carbon dioxid is chemically the same. Hence, the latter may rob and poison the former. In a tightly closed apartment with a gas stove without flue burning, the blood might be so surcharged with carbon dioxid and so deprived of oxygen that cyanosis might be produced, and even asphyxiation.

A few simple experiments will demonstrate the vitiation of the atmosphere by these heaters. The flame of a lamp or candle carried into a closed room where such a heater is burning will lose its brilliancy, and the flame will dwindle at a rate in keeping with the loss of oxygen and increase of carbon dioxid. If in such a room lime-water is exposed in shallow dishes, a thick film of calcium carbonate will be rapidly formed on the surface of the liquid.

SURGERY ONE HUNDRED YEARS AGO.

AN HISTORICAL STUDY

BY DR. GEORGE FISCHER.

DEDICATED TO THE GERMAN SURGICAL ASSOCIATION.

TRANSLATED FOR THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION
BY CARL H. VON KLEIN, A.M., M.D.

XVI.—DISEASES OF THE BLOOD VESSELS, NERVES AND SKIN. NEOPLASMS.

(*Continued from page 1016.*)

If from the teachings concerning carcinoma we select certain principles which are adopted to show a comparison of that time with today, we must confess that in this matter the surgery of one hundred years ago corresponds to our latest scientific conclusions. Between the two lie the erroneous teachings of the humoral pathologic school and the infinite and tedious labors of the microscopists. *Those fundamental principles, in which we agree with our forefathers are the following: Cancer is in the beginning a purely local affection; it must therefore be entirely and perfectly removed as early as possible. It is curable by surgery, and extirpation constitutes the only prospect of success; medicines are of no avail.*

The bulk of what was at that time written on carcinoma pertained to *breast cancer*, and it was here that those general principles found special application. Heister observed it most frequently in unmarried women between the ages of 40 and 50, as soon as menstruation became irregular. Richter considered it difficult to distinguish between harmless tumors and breast cancer and held this to be the reason that some surgeons had operated on this cancer with frequent success, while others at best rarely succeeded; he himself confessed that he had once mistaken a milk tumor for scirrhus. In respect to operation he distingushed three cases: 1. The painless scirrhus with the most favorable prognosis, absolutely demanded an operation. 2. In case of concealed cancer with unfavorable prognosis the operation is justified as the only help. 3. In case of open carcinoma, which allows almost no hope, no operation should be made. He nevertheless left a means of retreat and stated that case No. 1 was often unsuccessful, while on the other hand, 2 and 3 were occasionally operated on with success, and so the operation was justified in the two latter cases if it was permitted, withal. The result also depended on the more or less aggravated nature of the cancer, according to whether it was inherited or was of quick and spontaneous origin, or whether it had been very painful from the beginning, etc., in which case the prognosis became more unfavorable. In the case of scirrhous axillary glands, Heister attributed but little success to the operation, although he knew of isolated cases of cure by extirpation of the glands. In the operation, as stated, everything depended on completely eradicating the cancer and leaving behind no tainted particle. As contraindications, Richter noted the transition of the carcinoma to the intercostal muscles, ribs and pleura, also pangs in the breast and short breath, which indicated scirrhus in the lungs. Camper asserted that he had found that the change in the axillary glands was not the criterion of a later relapse, but that the safest guide was a piercing pain between the second and third ribs, where the art. mamm. int. passed outward; under these conditions he never operated. C. C. von Siebold would not operate in case [illegible] the tumor grown fast to the pector. maj., and Pouteau would not operate for breast cancer when no external causes existed, because he then considered that an affection of the uterus was the cause. Schmucker considered the reddening of the eyes with inflammation of the Meibomian glands as a safe indication that the cancer was no longer local, an assertion which Michaelis even at that time contested. Richter accomplished the extirpation with two crescent-shaped incisions which ran obliquely from the shoulder toward the under part of the breast-bone (Heister operated with a straight or crucial incision, B. Bell with a simple lateral incision, and Schmucker by the use of an awl-shaped instrument). and in case of a large tumor, even if a part of the gland appeared healthy, Richter always cut away the whole mamma, as did Bell in all cases. The skin was spared as much as possible and the hemorrhage was stopped, not too quickly but thoroughly, by means of ligature. Compression appeared to him not permissible, which by means of a sponge Theden and Schmucker declared to be sufficient. When the patient was not too weak Heister let a few ounces of blood flow in order to prevent inflammation and wound fever, and then for stopping the hemorrhage used a lint bandage with alcohol and puffball. He mentioned the ligature indeed, but did not recommend it, and censured Petit who used nothing to stop hemorrhage, but who immediately sewed up the edges of the incison. The closing of the wound was accomplished either with adhesive plaster (Richter) or by suture (Bell). They laid great stress on a quick healing by prima intentio, as it was considered the safest preventive of relapse. Indeed, Fearon extolled it so very much that he ascribed Monro's unsuccessful operations entirely to the fact that he filled the wounds with dossils and allowed them to suppurate. They extirpated the swollen axillary glands also, as well as the rest of the diseased mamma (J. L. Petit first). If a vessel passed through the axillary gland, a ligature was applied to it before they cut the gland out. J. L. Petit presented the best method for its eradication; he pressed the axillary gland out with two fingers, made an incision and peeled it out with the fingers. Gooch at one time took out nineteen scirrhous axillary glands. Tainted spots which arose in the wound during its healing were either well cauterized with a hot iron (Richter) or extirpated anew (J. Vogel and Sabatier), and to prevent their recurrence milk diet, water cure and artificial sores were recommended. If an operation was not possible, palliative treatment was the only resort, in which Richter had the sore bandaged with tar in order to diminish the pain and smell.

Cancer of the lips was frequently confounded with other sores and was considered less virulent than breast cancer. The external application of arsenic was heralded as the preferred remedy and, in general, corrosives. But the latter promised good results only when the ulcer could be entirely eradicated by one application. Richter and Bell preferred the knife or the scissors. Cancers which involved the whole substance of the lips, the former extirpated with a V-shaped incision, and if they affected only the external surface he severed it close to the skin. The Englishman laid great stress on always arranging the incisions so that it would be possible to close them by suture. Pott discovered a particular kind of a cancer of the scrotum and named it *chimney-sweeps' cancer*, because it was chiefly contracted by chimney-sweeps in consequence of the soot which accumulated in the crevices of the scrotum. It attacked first the under part, soon ate through the skin, rendered the testicles scirrhous and extended itself along the seminal duct into the abdomen. The only remedy consisted in removing the diseased part of the scrotum as quickly as possible, and if the testicles had been attacked even castration was no longer of any avail.

Encysted tumors, which Schmucker believed had become much more frequent since the time when ladies used so many hairpins in their head-dress and plastered the hair with powder and pomade, varied according to their contents; if fluid they were called meliceris, if pulpy atheromas, and if like fat steatomas. They were seldom successfully dispersed; the most frequent remedy was the operation in which the sac was not opened and was removed without leaving behind any of it. Bell attached no value to leaving it unopened and found it easier to open the sac, empty it and then cut it out. If the position of the tumor prevented a perfect extirpation the emptied cyst was left to suppurate. If the contents of the cyst were fluid, injections of irritating liquids or the use of a seton proved successful. They considered *exostes* as small sacs hanging to the sheaths of the tendons and containing matter like the white of an egg. They sought to disperse them into new places by friction or electricity, or to burst them with a blow from a hammer. As previously mentioned, Richter made incision or excision subcutaneously in order to avoid, as far as possible, the admittance of air. On the other hand, Bell did not hesitate in case of large tumors to remove the sac, intact and unopened, from the sheath of the tendon without further precautions. He described also the intumescence of the mucous sac and recommended a dispersion by means of friction, blisters or ruption and the keeping open of the swelling, also the drawing of a string through it. J. L. Petit gave especial attention to *telangectasis*, which had already been suggested to Heister by Dionis, and which J. Bell first accurately described. Both surgeons insisted on complete eradication with the knife. Z. Vogel accomplished many cures by cauterization. In a piece of linen cloth spread with plaster, a hole the size of the mother mark was cut and this was pasted on; then a dough made of equal parts of finely shaved Venetian soap and finely ground unslacked lime was applied to the sore through the hole, and so after twelve hours a scab was formed. The larger spots required repeated cauterizations.

XVII.—DISEASES OF THE HEAD AND FACE.

Skull fractures, trephining; Face wounds, artificial nose; Nasal polypus; Hare-lip; Cleft palate; Diseases of the teeth; Opening of the Antrum of Highmore and frontal cavity; Diseases of the tongue; (Ranula); Tonsils; Parotid gland; Operations on the ear.

To the favorite cases of surgeons belonged the *fractures of the skull*. The chief centers of interest were the indications for trepanning, of which three periods were distinguished in the second half of the eighteenth century. The first period commenced in England with Pott, who always trepanned (1760); the second, in Germany with Schmucker, who restricted trepanning (1774), and the third in France with Desault, who abandoned it altogether (1791).

Pott was impressed by the *times*. Undoubtedly he knew that centuries before, Lanfranchi of Paris († 1300), very seldom alluded to trepanning and considered an application of rose oil, properly bandaged, sufficient; Lanfranchi, however, in spite of his fame, was a very timid operator, so much so that he hesitated to draw molar teeth, and in cases of skull fractures invoked the help of the saints. On all sides Pott heard of the praises of trepanning, especially through the "Memoirs" of the Académie de chirurgie. The great J. L. Petit trephined every fracture, although not on account of the size of the fracture, but in order to relieve the pressure, to extract splinters, to remove the collected fluid, and prevent inflammation and suppuration. Of course, he knew of fractures which had been cured without trephining, but considered them exceptions. Useless, even harmful, he thought it in a case of concussion of the brain; but in extravasations, and the paralysis caused thereby, and in suppuration in the brain, although there might be danger of not locating the pus, he considered trepanning a necessity. He had already noted that in compression, insensibility sets in gradually, a fact to which Verduc and Boerhaave were the first to call attention, but in concussion suddenly. The same opinion was entertained by Quesnay. Although he also saw impressions cured without an operation, the cry still remained: always trephine, even if the bone is not broken, as soon as the injuries sustained by the head are serious. He described the fracture of the inner table, when the outer layer had remained entire, and also trephined in case of caries. Similar principles were taught by the military physician Ravaton. Proceeding from the idea that the symptoms and not the fracture indicated trepanning, the French operated in the event of the least injuries; LaMotte with the smallest fissures; Garengeot in case of counterstroke; Le Dran, mere concussions, when the skull was not injured. Most of the surgeons, especially Louis, were not in favor of trepanning the sutures nor the occipital bone on account of the great sinus. This prejudice Warner tried to dispel. Lassus successfully trephined the sagittal suture, Acrel the lambdoidal suture and the frontal bone, and Gooch the occipital bone. In Germany trephining was also the rage. Heister trephined in case of fractures, fissures, internal blood effusions when the skull remained entire, and in extracting splinters, portions of the skull that had been pressed in he raised by means of elevators. Perhaps warned by an inner voice, he gave the uncertain advice neither to undertake trephining without compulsion, nor to defer it when indicated by the symptoms. Altogether he expressed himself very reluctantly and declared that most of the operations proved fatal. It was very general to resort to repeated cupping in the treatment of the slightest cranial injuries, which method was most extensively employed by J. L. Petit; besides this, purgatives were frequently given, and poultices of warm wine applied so as to prevent the cold air from causing inflammation of the brain.

Then Pott came forward. Above all else, he designated all the dangers to which the dura mater is subjected in cranial lesions. The majority of these originate through the disturbance or the cessation of the communication that takes place between the pericranium and the dura mater by means of the many blood vessels. If a blow ruptured these vessels which connected the dura with the skull an effusion of blood was the consequence; but if they were only crushed, inflammation or suppuration would result, or the membranous covering and the dura mater be loosened from the bony case. Pott considered the loosening of the pericranium as a sign of the simultaneous separation of the dura mater. While signs of a depression were indicated by the escape of the blood soon after an injury, symptoms of inflammation and suppuration of the dura were noticeable a few days later. The differential diagnosis between concussion of the brain and extravasation Pott thought very difficult and the theory of distinction advanced by J. L. Petit and Le Dran regarding the setting in of unconsciousness, sooner or later, too uncertain. At all events a surgeon ought to prevent inflammation and suppuration; or if this was no longer possible, procure a free passage to drain the pus. The former was accomplished by strong bleeding, the latter by trephining. Pott trephined even the simplest fractures of the skull at once; only special circumstances influenced him to defer an operation; not, however, on account of the fracture, which necessitated no operative interference and could not be cured thereby, but on account of the blood effusion and its evil effects. The inflammation of the dura mater appeared to him the most serious one. It covered the ulcer and hindered the spontaneous bursting of the same; so this circumstance alone justifies an early trephining of every simple fracture of the skull. Besides, out of every ten fractures seven are accompanied by urgent symptoms, so that in most cases immediate operative interference is called for. Although Pott had to admit having unnecessarily trephined when unsuccessful, he contended that the few cases did not overthrow the rule: "Better trephine two patients unnecessarily than let eight die for want of it." Nor did he deem it so dangerous, although the uncovering of the dura mater was not an indifferent matter to him; yet the danger arising therefrom did not compare with that caused by neglecting to trephine. If the escaped blood gathered under the dura mater, he opened the same by a cross incision. When no blood was found underneath the fracture, trephining was again resorted to; the sutures and upper portion of temporal bone only when necessary, but then it must be boldly opened. Depressions demanded the same treatment as the fractures. If the injury is accompanied by depressions, an operation is performed to raise or remove the depressed fragments, and on the uncovered dura mater is lightly placed some soft dry charpie held in position by a nightcap or pocket handkerchief instead of the usual uncomfortable head bandages. The audacity with which Pott trephined day after day is astonishing and if he did not detect the pus, the drainage of which he considered the only remedial agent for the sustenance of life, he followed up the first operation with a second and third. That his trephining operations met with more success than attended those in the hospitals now-a-days was probably due to the less frequent occurrence of pyemia at that time, and if the question is put why Pott succeeded so much better than Desault, we must consider that he employed immediate trephining with every fracture before inflammation set in.

Naturally, the example of trephining set by so prominent a surgeon was followed everywhere. How could an unknown English navy surgeon, John Atkins, gain the upper hand with his little article against trephining in 1742? He received no recognition whatsoever. Also in Germany trephining continued to flourish. In 1763, Simon Pallas feared no suture, no sinus, no fontanelle; with depressions he tried his luck by using strong adhesive plasters and cupping glasses, trephined also in case of caries of the inner table and in case of headaches which had not yielded to other remedies. Similar extensive views were entertained by Bilguer (1763–71). Among other things he said: "Mr. Martini tried to restrict trephining, as I tried to do likewise with amputating; and what physician and surgeon as well as every other human being does not exclaim with me: Would to God that we might be spared, if not entirely, at least for the greater part, trephining and amputating and all other surgical operations! However, since greatly improved in knowledge by my varied experiences, I believe that my reasons are well grounded for declaring trephining to be very often necessary and useful, on the other hand, amputating is very often unnecessary and useless. Therefore I have not been able to speak of them in any other way than I have done." Bilguer trephined fractures as well as depressions, the frontal bone as well as the occipital, and cut through the hard membranous covering of the brain, when he suspected extravasations underneath it. Having cured two cases without trephining, he believed that with the same the wounds would not have been more dangerous. He trephined often and betimes, but acknowledged that the operation was not always necessary when the fracture was large and the fragments of bone very loose. It is worthy of note, that not even the simplest injuries were treated lightly by him. He laid great stress upon pure air, therefore ordered all patients suffering from injuries of the head to be protected from the evils of hospital fevers and foul air, by separating them from the other wounded and sick, as was done in most of the military hospitals. Theden considered the trepan an indispensable instrument; without it, death was certain. What was accomplished in trephining by the two military physicians during the Seven Years' War can easily be imagined if we repeat Dr. Baldinger's remark: "Every cranial injury, be it a deep wound, a contusion, cut, blow or a wound caused by a grazing bullet, absolutely necessitates an operative interference." He upholds Bilguer and Theden in their reputation of having generally introduced this less cruel, but ever harmless and so often life-saving, operation. The end of Pott's period of universal trephining came with J. Hill, whose ideas, to a certain extent, clashed with those of his countryman. Slight depressions he did not raise, because he considered forcible elevation very dangerous. Bromfield opposed the prevailing idea that concussion of the brain required great draining and recommended opium in the form of Dover's powders instead of it.

The second period is represented by Schmucker, to whose immortal merit be it said that he introduced cold compresses for injuries of the head and restricted trephining. What an interest our countrymen took in this class of injuries by erecting a special field hospital for those who received injuries to the head during the siege of Schweidnitz in 1762, has been mentioned heretofore. In the beginning of the Seven Years' War, he trephined as often as any one else, and even on one occasion for headache which had set in after a simple cranial wound, the bone having remained unscathed. But he knew that the indications for trephining were still very uncertain, and were mostly made in the study room where one writer copied from the other. His first twelve cranial injuries were comparatively mild cases; either a simple lesion of the soft parts caused by a shot, or a slight exposure of the bones; there were no depressions or fractures. The concussions were not violent, the patients would have been able to go about in a few days and attend to business. Schmucker trephined them and saw all of them die. "This moved my whole soul, and every physician who has humane feelings would have been affected as I was under the circumstances, when in spite of all pains and care he could not save the patient, but must be a mere spectator to the rage of the disease. . . . I discovered a new remedy. . . . This discovery and its successful results following, gave me great joy and pleasure." His physiologic observations which led to his applying cold water and the manner in which he used it have been mentioned in the 14th chapter. When a patient with an injured head came to the field hospital, the wound was enlarged and dressed; then he was bled to the extent of sixteen ounces, which operation was repeated several times if necessary. The head was now enveloped in a thick flannel steeped in his "fomentation" and lightly wrung out; this process was renewed every hour. Internally, saltpeter, neutral salts and purgatives were given, also enemas. With these remedial agents, Schmucker saw exposure of the bone, impressions, depressions, and even fractures heal. Yet in connection with the last kind of injury, he employed trephining whenever necessary, occasionally from two to five times and in a case of caries as often as eleven times in four weeks. But in this instance, the patient was very little discommoded and could seldom be induced to lie down immediately after an operation, but instead went to market an hour afterward to make his purchases; he died a week after the eleventh operation. A patient had suffered with an intense headache in the same spot for about a year; so Schmucker and Meckel suspected a caries of the inner table or an ulcer in the brain. They trephined him, but found the bone entire. "We looked at each other in blank astonishment." Without having a knowledge of Schmucker's cold compresses, a second blow was dealt Potts's teachings by William Dease of London in his "Observations on the Wounds of the Head," 1776. First of all he proved that the inflammation and suppuration of the dura mater was not the most frequent cause of the serious cases. This suppuration was not so much to be feared and could be removed by trephining; he also did not believe that on account of the blood vessels connecting the dura mater and pericranium, the injury caused a suppuration of the former. He laid the cause of death to the inflammation and suppuration of the pia mater and the brain itself. But as the external symptoms are not manifested until pus has formed, bleeding, Dover's powders and trephining are of no consequence. Since by means of the last agent the pus could not be drained off, because it was not in clots, but mostly spread over a large portion of the brain, hence in most cases an operation was of no use. Methods of treating cranial injuries were thus improved by Schmucker and Dease, who had discovered a new method of determining the seat and cause of fatal cases. In 1778 Metzger of Königsberg opposed Pott and did not believe in trephining every fracture of the skull. Very decidedly did Richter confront his teacher, defended the teachings of Dease and adopted Schmucker's methods. From his ever-regulating hand the German surgeons received a new teaching with great restriction of trephining. Not a simple fracture of the skull, not a concussion of the brain, not the inflammation of the two membranes, not the suppuration of the pia mater require trephining; but the suppuration of the dura. Richter advised every surgeon to use cold poultices from the very beginning in minor cases of cranial injuries, in order to avoid inflammation. Extravasations usually had to be trephined; however, if there be no imminent danger, dispersion, which had already been carefully observed, should be tried. At that time this method was a great improvement, for it was this very circumstance of not knowing how to get rid of the wound secretions, there being no drainage, that made trephining indispensable. Richter absolutely rejected Pott's idea to immediately trephine all fractures and compressions and at all events waited until there were signs of suppuration and extravasation. By means of the operation inflammation could not be prevented; on the contrary it was promoted and accelerated by the irritation which it caused. If, however, the seat of the extravasation was suspected, which was often a very difficult matter, trephining should not be deferred long; however, it should not be done at random. Although it was of consequence only in the suppuration of the dura mater, yet operative interference was necessary because it was not known in which one of the membranes the pus existed. Bleeding, cold applications, purgatives and emetics Richter considered the principal remedial agents in cases of fatal inflammation of all cranial injuries with or without fractures. Only in concussions was bleeding a bad thing; emetics, though, were excellent. Not until all remedies failed was trephining resorted to in concussions of the brain (Hill). Depressions of the skull with bad symptoms required trephining, otherwise not. For slight impressions were not fatal; the brain soon became accustomed to these and the patient could live the rest of his life with them; besides, the bones often of themselves rose again. Desault maintained a similar opinion. Further signs for an operation were fractures of bones that stuck fast, but were foreign bodies as soon as there were any symptoms. Whenever possible, Richter avoided the sutures, the temporal, frontal and occipital bones, yet positive contraindications were not given by these bones. He also criticised the exposure of the entire fracture by means of the cut through the integument, which need be no larger than necessary to place the top of the trepan. His fundamental principles coincided with B. Bell's and partially with Louvrier's and Mursinna's, although the latter two restricted trephining still more (1800).

(To be continued.)

SOCIETY PROCEEDINGS.

Southern Surgical and Gynecological Association.

Proceedings of the Tenth Annual Meeting, held in St. Louis, Mo., Nov. 9, 10 and 11, 1897.

FIRST DAY—MORNING SESSION.

The Association met at the Southern Hotel, and was called to order by the President, Dr. GEORGE BEN JOHNSTON of Richmond, Va., at 10 A.M.

Prayer was offered by the Rev. S. J. NICHOLS, D.D. of St. Louis, after which an address of welcome was delivered by Hon. CHARLES NAGEL.

President JOHNSTON responded to the address of welcome on behalf of the Association.

After announcements by the Chairman of the Local Committee of Arrangements, Dr. H. H. MUDD, the reading of papers was begun.

Dr. C. A. L. REED of Cincinnati read a paper entitled

GALLSTONES IN THEIR RELATION TO CANCER OF THE GALL TRACT.

The paper was based on a report of four cases in which distinct gallstone history had preceded the history of malignant disease. The diagnosis had been confirmed in all of them by exploratory incision and in two of them by autopsy.

Case 1.—Woman, aged 52 years; had hepatic colic during five years preceding, associated with all of the usual gallstone symptoms. During the preceding thirteen months pain in the right hypochondriac region had been constant. Within the preceding six weeks persistent jaundice had developed. Globular tumefaction was felt below the costal margin. Exploratory incision revealed primary carcinoma of the gall bladder and of the gall tract with secondary development in the liver. Diagnosis was confirmed by autopsy.

Case 2.—Male, aged 60 years; had gallstones for twenty years; confirmed by their frequent passage *per vias naturales*. Patient had undergone rapid emaciation and during the preceding month pain had become constant. More latterly he became pronouncedly jaundiced. No physical symptoms could be detected. Exploratory incision revealed carcinoma of the gall bladder and gall ducts with secondary nodules in the liver. A calculus was found in the common duct and disintegrated by needle puncture. Primary recovery with amelioration of all symptoms, followed by death four months later. No autopsy.

Case 3.—Woman, aged 45 years; had had hepatic colic for several years. During the preceding six months she had been profoundly jaundiced; lost flesh rapidly. Examination of the blood revealed marked cholemia. There were no physical symptoms in the right hypogastrium. Exploratory incision revealed induration about the head of the gall bladder and common duct, to both of which the duodenum was firmly attached for a distance of several inches. Calculus could be felt within the common duct just within its orifice. This could not be dislodged by prudent pressure or disintegrated by needle. It was delivered by incision through the duodenum. The patient never rallied, but died within thirty-six hours after the operation. No autopsy.

Case 4.—Male, aged 52 years, constant drinker; had had severe hepatic pain during preceding fifteen years; last attack was persistent and continued for over six weeks. In addition to the usual symptoms he had a vacillating temperature and sweats. Operation revealed empyema of the gall bladder with induration at its ductile end. The gall bladder was stitched to the abdominal incision and drained; death one week later. Autopsy revealed carcinoma of the ducts at their juncture. Numerous small calculi were found in the hepatic duct well up in its main trunk and in a number of its twigs. Multiple abscesses were found in the liver substance.

These cases have a suggestive significance and point to an etiologic relationship. This is explained by the result of persistent irritation of the foreign bodies upon the mucous surfaces, inducing hypertrophy, cell proliferation, and in the event of the existence of original tendencies to cancer of antenatal origin, they induce rapid development of the malignant neoplasm.

Dr. EDWIN RICKETTS of Cincinnati said the important question of the relation of gallstones to cancer of the bile ducts was now receiving the attention due it. In many of these cases cancer had been found near the duodenal end, and the malignancy which results from the presence of gallstones is of such a nature that in many instances the surgeon could not get at the bottom of the pathologic condition except by an exploratory incision. He reported two interesting cases. He said Courvoisier had found malignancy in seventy of eighty-four cases of gallstones, while Bradrowski had found forty cases of cancer straight.

Dr. JOSEPH EASTMAN of Indianapolis spoke of a case that had come under his observation within the last two weeks, which confirmed the remarks of the essayist. He operated on a patient who had symptoms of gallstones and the patient's friends insisted that he had passed several of them. The gall bladder was thickened and indurated. So far as he could determine, there were no gallstones, but advancing malignant disease, which will ultimately destroy the life of the patient. The gall ducts were obstructed. He did not remove a section for microscopic examination. He believes that cancer here, as in the uterine cervix, is often the outgrowth of prolonged localized irritation.

Dr. JAMES T. JELKS of Hot Springs, was fully satisfied that cancerous troubles can occur from chronic irritation as has been said. Thus far, no specific organism had been shown that produces cancer. While his experience was not large in this direction, he had seen cancer of the uterus unmistakably produced by gallstone infection; hence the deductions of the paper in urging operative interference in all these cases in order to prevent carcinoma of the liver were prudent. The statistics were a revelation to him, as he did not know that 90 per cent. of the cases of carcinoma of the liver were preceded by a history of gallstones.

Dr. Rufus B. Hall of Cincinnati, expressed himself as being firmly convinced that the deductions from the paper would be sustained by future work along this line. Nine cases tabulated by him confirmed the deductions of the essayist. He cited one case. Eight years ago Drs. Reed and Ricketts saw him do a gall bladder operation on a patient who had given a distinct history of gallstone colic for fourteen years. There was occasional icterus, and then a period of comparative freedom from it for a half a year, and then there would be another attack of gallstone colic. The last attack came on four or five months preceding the operation, when the patient became icteric, and so remained until surgical interference was resorted to. She had a distended gall bladder and enlarged liver. There was some doubt as to whether or not there was a complication other than an impacted gallstone in the common duct. Operation revealed a distended gall bladder with four or five stones in it and cancer of the gall ducts. Undoubtedly the cancer in this case was of recent development, dating perhaps from the patient's last illness. Dr. Hall thought that if she had been operated on preceding the last eight months of her illness cancer might not have developed.

Dr. A. M. Cartledge of Louisville, said that while he did not question the practical nature of the deductions drawn from the paper, yet it was much easier to establish a causative relation between cancer and gallstones than it is between gallstones and cancer. When the frequency of gallstones is considered, and that they occur in perhaps one case in three of every individual, and that carcinomatous processes in the gall ducts are among the most frequent of all causes of gallstones, it was not at all unlikely that in reasoning on this subject the cart was sometimes placed before the horse. When we have a positive well established history of gallstones for several years and an individual develops malignant disease of the gall bladder, the inference was strong that there might have been a relation between the previously existing calculus trouble and the subsequent malignant disease. In many cases presenting a history of the passage of gallstones, the patient may have had beginning carcinoma of the ducts for two or three years previously. He endorses the views of the essayist as regards operative interference in cases of gallstones.

Dr. L. McLane Tiffany of Baltimore, agreed with Dr. Cartledge that the causative relation between gallstones and carcinoma was not well established at the present time; but that carcinoma was accompanied by gallstones and found frequently to exist was well known. These cases should be operated upon sooner than is usually done.

Dr. Thaddeus A. Reamy of Cincinnati, took a more conservative ground than the preceding speakers, and said that the Association ought not to go on record to the effect that because gallstones are associated with cancer the abdomen of every man or woman must be cut open lest he or she, as the case may be, may have cancer. Taking the rural and city population, he ventured the opinion that in not more than 15 or 20 per cent. of cases of gallstone was cancer associated with this condition. The subject would have to be studied more carefully and thoroughly before the proof is convincing to him.

Dr. Reed, in closing, re-emphasized the significance of the persistent coincidence of cancer in long-standing gallstone cases. His own brief experience embraced cases in which there had been long-standing antecedent gallstone history.

DISPOSAL OF THE STUMP IN APPENDICITIS OPERATIONS

was the title of a paper by W. D. Haggard, Jr., M.D., of Nashville, Tenn. The author considered this disease pre-eminently a surgical affection. Early surgical opinion in making a diagnosis was essential. Surgical isolation of the infected appendix was as sound and imperative a practice as the hygienic isolation of any of the infectious diseases. The author advocated early operation, and mentioned Mayo, Robson, Willy Meyer and McBurney, as advocating prompt operative interference. The more imperative and explicit operative indications were specified.

The pioneer method of ligating the appendix like an artery or the stump of an ovarian tumor or appendage pedicle, was shown to develop therefrom by reason of infection of the stump, etc. Subsequent perforation after simple ligation occurred sufficiently often to cause the abandonment of this method. The various methods of disposing of the stump by invagination were discussed, and the modifications and technic employed by Van Hook, Dawbarn, McBurney, Murphy and Morris were described. The ideal of all surgery was completeness applied to the surgery of the appendix, which was that of total extirpation of the organ. The author stated that it had remained for Deaver to practice this method in suitable cases, which is as follows: After freeing the appendix from adhesions and meso-appendix, the cecum is stripped of its contents and grasped between the fingers and thumb of the left hand, the appendix being held by forceps and cut off flush with the colon, and after being amputated at the site of its former junction is united by continuous Lembert sutures, while the cecum is still held securely with the left hand just as in a gunshot or stab wound of the intestine. Sutures may be disposed in two layers, first uniting the edges of the wound, and second approximating the peritoneal covering to the cecum over it. This method was not applicable to cases where the cecum is bound down by adhesions preventing its delivery in the incision. It is necessary to prevent the escape of colon contents by accurate suturing of the cut end.

Total excision of the appendix with closure of the hole in the head of the colon was said to do away with the following dangers: 1, subsequent perforation of the stump under the ligature from infection in its own cavity; 2, abscess of the wall of the cecum from invagination of the infected stump; 3, continuance of infected process from stricture in the stump between distal ligature and the proximal opening of appendix into the cecum; 4, imperfect invagination with incomplete drainage of the stump on account of the cecal wall being thickened and stiffened with inflammatory exudate.

The author reported five cases in which he has recently employed this method with entire satisfaction.

Dr. George H. Noble of Atlanta followed with a paper entitled

REPORT OF FOUR CASES OF ABSCESS OF THE UTERUS.

The first case was of puerperal origin, the operation being done at the end of the second week. There was a pus tube and abscess of the left ovary. The appendages on the right side were normal. After separating extensive adhesions for unilateral disease, an abscess of the fundus uteri about the size of an ordinary lemon was discovered, which was excised, curetted and cauterized with carbolic acid. The cavity extended from the median line to the stump of the appendages on the left, which was turned into it and fastened with sutures to prevent the formation of dead space. A glass drain was dropped into Douglas' pouch, after flushing the abdominal cavity. This woman made an uneventful recovery, and has been well for two years without any pelvic disturbance. Three similar cases were reported in detail by the author.

The four cases show what any surgeon will sometimes do for a septic uterus when given a chance. They also support the view that it is not always necessary to extirpate the womb in suppurative inflammation of its parenchyma, and such operations should be more closely confined to cases in which the uterus is thoroughly septic or riddled with abscesses. The latter are rare, fortunately, for they do not stand operations well. The cases also show that infection of a puerperal uterus does not necessarily mean that the entire organ is hopelessly contaminated, but that intense foci may be circumscribed by nature and removed without sacrificing the organ.

Dr. A. M. Cartledge endorsed the method pursued by the essayist. He thought the recovery of four women with systemic infection by such a procedure showed the wonderful power of the peritoneum, if drained from below, to take care of a violent form of sepsis. The results following this method were better than those of hysterectomy for infected uterus complicating childbirth or abortion.

Dr. J. Wesley Bovee was pleased with the advanced position taken by the author of the paper. Gynecologists had to fear, however, the future usefulness of the uterus. It was not so much the destruction of tissue and the formation of abscesses, but the resulting cicatricial tissue and connective tissue formed might interfere with the function of the uterus in subsequent labor. It might tend to the production of rupture of the uterus. At the same time, these points were not of sufficient importance to justify operators in not following out a conservative procedure such as had been described.

Dr. James T. Crofford of Memphis, said in cases of abscess of the uterine wall originating from the mucous membrane, if the cervix was kept dilated, the uterus freed of everything with a curette, and he does not hesitate to use a sharp curette in these cases, and thoroughly cleansed and packed with gauze, these abscesses would open into the endometrium, followed by relief in the majority of cases.

Dr. Richard Douglas called attention to the kind of germ that produces infection. In well known streptococcus infection it was not the tendency of inflammation following this form of infection to circumscribe itself. It was diffuse infection. In treating cases of infection following abortion or full term labor he had used the Carossa method with decided benefit.

Dr. W. E. B. Davis of Birmingham, said that uterine abscesses following abortion or the puerperal state could be treated successfully by incision and drainage in a good proportion of cases, even though the abscesses may have extended beyond the uterus. Illustrative cases in which this treatment was resorted to were cited.

Dr. J. G. Earnest favored an exploratory incision to ascertain whether or not the patient was a fit subject for the method of treatment pursued by Dr. Noble. In the event the case was not suitable for the application of this method, very little damage was done by such an incision.

Dr. R. M. Cunningham said it was extremely difficult in general surgery to get primary union by curetting and disinfecting an abscess. By curettement and cauterization it was hard to destroy the staphylococcus, and much more so the streptococcus, which perhaps extends beyond the abscess wall and continues its infective influence.

Dr. Noble, in closing, emphasized the point that the uterus was the seat of infection and not the appendages. Only in cases where there are one or two, or possibly three abscesses, is this method of treatment applicable.

A STUDY OF RETROPERITONEAL NEOPLASMS AND SUPPURATIONS WITH SPECIAL REFERENCE TO DIAGNOSIS.

By Dr. Richard Douglas of Nashville, Tenn.

The author accepted the definition of Mr. Lockwood for retroperitoneal neoplasm, namely, a solid or cystic tumor growing behind the peritoneum into the folds and not connected with any of the great retroperitoneal organs.

Pathology.—The type of tumor usually encountered in the retroperitoneal space belongs to the connective tissue group. A careful study of the cases shows that they are of a mixed variety, the predominating type being sarcoma and lipoma, but occasionally fibroma and myxoma are met with. An analysis of the twenty cases of solid retroperitoneal tumors collected by Rogowski showed sarcomatous tissue in every one. The peculiarity of retroperitoneal sarcoma is that it is encapsulated.

These tumors occur after maturity, from twenty-eight to fifty-nine years. Mudd's patient, the oldest on record, was 71 *years of age. In one case reported by Austein, the patient*, a female, was 4 years of age, an age in which sarcoma is very rarely observed.

The duration or life history of retroperitonal tumors is usually about six months, though some cases have lasted for years.

Causation.—There is no recognized cause for these growths, yet in some cases a malignant growth appears as secondary to some local injury or suppuration. The two special symptoms that occur in the history of postperitoneal growths are intestinal obstruction and edema of the extremities.

Retroperitoneal cysts.—A genetic classification of retroperitoneal cysts is more difficult, in view of our very meager knowledge of the subject, than that of solid neoplasm.

The author then considered at length cysts of the pancreas.

A clinical feature of intraperitoneal growths is that the area of resonance varies with the position of the patient; consequently it is not surprising that many a dry tap has been made through a failure of recognized clinical peculiarities.

While not an advocate of the use of the aspirator in intra-abdominal diagnosis, yet under proper conditions the author thinks this instrument will reveal valuable evidence, not only as to whether the growth is solid or cystic, but as to its nature. In retroperitoneal sarcoma aspiration reveals only a little blood or blood serum in the needle. This sign enabled Weir and Bull to correctly diagnosticate a case reported by Devlin.

Dr. J. Wesley Bovee of Washington, D. C., contributed a paper on

TUBAL AND OVARIAN HEMORRHAGE RESEMBLING RUPTURED ECTOPIC PREGNANCY.

The author said that a few years back pelvic hematocele was a condition that every practitioner met occasionally, and many were the supposed causes of it. When the subject of ruptured tubal pregnancy was so universally taken up, some of the most aggressive investigators told us to search in every case of pelvic hematocele and we would find a ruptured ectopic pregnancy. This dictum, though not endorsed by all observers, found a ready following, and to this time the majority of students of diseases of the female pelvic organs have accepted it. Many cases have been reported in which a presumptive diagnosis of ruptured tubal pregnancy has been made, cases in which such symptoms as shock, sharp pain, irregularity of menstruation, even to amenorrhea, the presence of a small tumor in the pelvis, and even death were present, and yet the autopsy has revealed no pregnancy, but instead a hemorrhage from a Fallopian tube or an ovary, or both. The speaker offered conclusive evidence against the positive statements that have gone out that we will always find this condition in these hemorrhages. There were many instances in which women were deeply wronged by these diagnoses. Oftentimes the hemorrhages have occurred in virgins at a very young age and in widows above reproach. These hemorrhages result from ectopic pregnancy, from malignant disease of the uterus, appendages or rectum; from varicosed veins in the broad ligaments; from disease of the appendix; from inflammatory disease of the tubes and ovaries and many other causes.

The author's remarks were restricted to disease of the appendages, and he cited a case in detail to exemplify them.

An examination of the specimen removed by operation showed it to be a hemorrhagic cyst of the ovary that had opened into the peritoneal cavity, and was connected with the cavity of the Fallopian tube by a sort of canal or sinus formed by adhesions over the shallow groove of the ovarian fimbria of the Fallopian tube. The remainder of the fimbriated extremity was closed by adhesions. The tube was distended by a large blood clot, quite dense and dark, and which upon section and careful separation showed nothing but blood. The wall of the cavity left after removal of the clot from the tube was perfectly smooth and even. As a result of careful examination, including the use of the microscope, the case was pronounced one of hemorrhage without the presence of pregnancy.

Dr. Richard Douglas had twice removed hematosalpinx *(unilateral) in which there was no possibility of extra-uterine* pregnancy. He also reported an interesting case of blood cyst of the ovary in which there was no disease of the tube and no special cause giving rise to it. Usually the cause of blood cyst of the ovary was torsion of the pedicle. This was not the cause in the patient he had operated upon.

Dr. James T. Crofford reported a series of anomalous cases of extra-uterine pregnancy before the Tennessee State Medical Society this year. One of the cases was complicated by an ovarian cyst as large as a good-sized fist. He had come to the conclusion that these cases were all due to ectopic gestation. Personally, he was obliged to the essayist for disabusing his mind of this. He had examined the specimen of Dr. Bovee with a great deal of interest and believed there was no pregnancy connected with it.

(To be continued.)

American Public Health Association.

Twenty fifth Annual Session Held in Philadelphia, Oct. 26-29, 1897, at the Hotel Walton.

(Continued from page 1019.)

Tuesday—Evening Session.

A formal opening of the session was held, to which the public were invited. Prayer was offered by Rev. Wm. N. McVickar, D.D., Rector of the Church of the Holy Trinity, Philadelphia. Dr. Benjamin Lee, the Chairman of the Committee of Arrangements, in the absence of the Governor of Pennsylvania, welcomed the Association, and was followed by The Hon. Charles F. Warwick, Mayor of the city.

THE ANNUAL ADDRESS

was then delivered by Dr. H. B. Horlbeck, Health Officer of the city of Charleston, S.C.

He expressed his appreciation of the honor conferred by his election to the position of President. The Association had happily chosen this city as its place of meeting, a city which for a century has held the proud distinction of being the foremost and best in professional attainment; a city which has always been in the front rank of the noblest aspirations in a calling where the first requirement is an abnegation of personal and selfish consideration, which exacts devotion to the wants of mankind when they become sufferers. Along the century's diapason the great names of Rush, Wood, Chapman, Gross, Leidy, Jackson, Mitchell and Mutter come down to us in consonant accord with the best and truest ideals of humanity. From these and other great worthies of this city, the wisdom of the ages has been given to thousands of our colleagues who have glorified our teachers by constant self sacrifice and laborious loyalty to their alma mater. To Philadelphia we are under obligations for the establishment, during the first half of this century, of the best schools of medicine in our country. The lights in the sacred fame of medical lore have been kept constantly bright, and today Philadelphia is second to none in her great schools for the propagation of medical knowledge. From the earliest dawn of history we learn that the nomads, and later the denizens of cities, exercised care in removing from their surroundings the dangerous accumulations resulting from congregated habitations. From the use of the simplest methods which gradually increased in scope as modes of living became more complete in character, the highest scientific knowledge is now demanded to meet the requirements of the great cities and peoples of the earth. The theories based on the humors of the blood have given way to a knowledge of the denizens of the blood, which are being recognized as surely as the flora and fauna of our fields. The microscope gives us the key-notes of our temporal welfare. Pasteur says: "wherever and whenever there is decomposition of organic matter, whether it be in the case of an herb or an oak, or worm or whale, the work is done exclusively by infinitely small organisms. They are the important, almost the only agents of universal hygiene; they clear away more quickly than the dogs of the streets of Constantinople or the wild beasts of the desert, the remains of all that has had life; they protect the living from the dead."

He next gave in some detail a history of the Association since its organization in 1872, and now, after twenty-five years, nearly two thousand names are enrolled in its membership. During its existence some of the most important discoveries in the domain of medicine and surgery have been made, and the science of bacteriology has had its birth and development. Nearly every one of the score or more of bacteria that are pathogenic, and that seriously menace human life, have been found and described during the existence of this Association. Since the last meeting at Buffalo the method of diagnosing typhoid fever, as discovered and described by Widal of Paris, has been elucidated by Dr. Wyatt Johnston of Montreal. He has shown that when a drop of blood from a typhoid fever patient is brought in contact with a typhoid fever bouillon culture of the bacillus typhi abdominalis there is an agglutination of these bacilli and a cessation of their mobile characterization. This method is now being utilized in a number of cities, and arrangements have been made whereby physicians can send a drop of blood, moist or dry, in a suspected case of typhoid fever, to a bacteriologist, who will in a few hours determine the disease. During the life of the Association the processes of taking care of contagious diseases have entirely changed. It is now the essential feature of the practice in all communities to confine all such cases to the individual affected. The water supply of all communities is one of the most important matters, and sanitarians will be surely called on to care for it. Whether the source of supply be shallow or deep wells, cistern, river or lake water, each involves special problems in arranging to free them from polluting causes. Parkes estimates 12 gallons daily as about the quantity required by a man for cooking, potation, ablution and house-washing purposes. London finds 35 gallons per head none too much, and some cities in our own country, notably Philadelphia, are furnished with over 200 gallons per head per day. An abundant, increasing supply of water carries in its train incalculable possibilities, not only for cleanliness, but for the development of the industries which will employ tens of thousands of people who may thus obtain means of occupation for existence, and with good maintenance increase their powers of resistence to disease. It would seem needless to call to the notice of the members the great issues involved in a pure water supply. free from disease-producing germs. Diseases which are appalling in their death rate are transmitted principally by water. The most common mode of conveyance of cholera and typhoid fever is by water, and many other diseases are believed to be so transmitted. Greater purity is demanded every year. When the supply is taken from lakes every source of pollution is removed; when taken from a river the problem is more intricate and vexatious, as it involves the prohibition of cities situated further up from using the river as a dumping place for sewage. Where rivers must be so relied upon, filtration, mechanical or artificial, must be resorted to, and a daily microscopic and chemic examination of the water be made to ensure that the water is free from dangerous bacteria or poisonous compounds.

He next referred to the great change that has been made in the United States during the last twenty five years in quarantine methods, especially in shortening the time of detention, and the methods of disinfection. Detention has been shortened from twenty-five to fifteen and ten days, and in Southern ports for yellow fever to five days. This has been largely due to the energy and sagacity of a member of this Association, Dr. Joseph Holt, the distinguished ex president of the Louisiana State Board of Health, in his efforts to protect the port of New Orleans from yellow fever. Many methods have been in use for disinfecting vessels at the New Orleans Quarantine Station for the last twenty-five years, among which are the filling the holds of the vessels with sulphurous acid gas; raising the temperature to 350 degrees F. and placing textile fabrics in a solution of mercuric chlorid. In 1886 a heating chamber was devised to be used in conjunction with mercuric chlorid and sulphur fumes, the latter being driven into the holds of vessels by a revolving fan. Many improvements have since been made, and a plant is now in use by which the temperature is raised to 230 degrees and the personal effects of the passengers are disinfected with quickness, certainty, and with little injury. It is estimated that over 95 per cent. of all the yellow fever that has reached this country has come from Havana. A committee of this Association has been appointed to bring this vital question before the governments of this country and urge the governments of the countries interested to prompt action in this matter. This would seem to be the occasion when not only the recommendations of our committee on yellow fever should be carried out, but that this body should make a demand on our general government that a commission of expert bacteriologists should be sent to Havana and Rio, and be kept there until the materies morbi have been discovered, until the secrets of this marvelous disease have been unfolded. The examples of other countries in the solution of the problems of cholera, tuberculosis, bubonic plague and leprosy may be noted. Why should we not solve the problem of yellow fever? A systematic effort continuously made will be crowned with success. He recommended that a committee from this body be oppointed to wait upon the President of the United States to carry out the idea.

He then referred to the progress being made in conquering consumption in the discovery of the tubercle bacillus by Koch. There is in every land a profound recognition of the responsibilities of the governing classes, and that a preventable disease should be prevented. The State Board of Health of New York has declared tuberculosis to be a preventable disease, an infectious and communicable one, and provides for a detailed report of all cases attended by practitioners in that city. He commended the action of that board to every sanitarian in the land who is charged with the protection of the public against the spread of preventable diseases.

He then referred to the experiments of the State Board of Health of Massachusetts at Lawrence on the utility of filtration of the water supply for the removal of typhoid fever germs; the average was the removal of over 98 per cent. In looking over the work of this Association during these twenty-five years we have reason for exultation and pride. We bequeathe this noble heritage to our successors in this work. We transmit to them the light that was handed down to us from our predecessors, and we bespeak in return for this great cause the same loyalty and untiring devotion that we have given it.

WEDNESDAY—MORNING SESSION.

The Association reassembled at 10 o'clock. A number of new members were elected and the vacancies in the Advisory Council were filled, all old members who were present being reappointed.

Dr. **HIBBERT HILL**, of the Board of Health of Brooklyn, read a paper on

ANALYTICAL WORK ON PUBLIC WATER SUPPLY,

showing an instrument for the collection of samples of water for chemic, microscopic and bacteriologic analysis. This appatus, designed by Dr. Hill for use in the Rockville Center Laboratory, established for the sanitary supervision of the Brooklyn water supply, has stood the practical test of constant use for a year. Its strength, simplicity and ease of manipulation commend it to those who require samples of water from ponds, rivers or streams where a sample of the water is desired at depths from two or three inches to fifteen or twenty feet. The depth, in fact, is only limited by the convenient length of the pole attached. The apparatus may be further modified so as to allow of collection of samples at any depth by the use of cords and weights.

The apparatus consists of a holder for the bottle and a device for the withdrawal of the stopper, when the bottle is submerged to the desired depth.

The holder is shaped like half a hollow cylinder and is of such dimensions as will fit the bottle usually employed. It has a circular bottom with a raised edge and upon this the bottle rests. The holder is made of galvanized iron. The bottle is secured to the iron case by a strap of brass, hinged on one side of the holder and fastened by a catch on the other. The bottom piece of the holder is perforated to permit the ready passage of the water through it, and in consequence there is greater ease in handling when under the surface. Holes at the side on a level with the mouth of the bottle when it is in position, allow free access of the water from every direction, while the bottle is being filled.

The device for the withdrawal of the stopper from the bottle consists of an upright rod of wood passing through two brass rings, which are rigidly secured at right angles to the inner side of the iron holder. These supporters are so placed as to center the end of the wooden rod over the mouth of the bottle. The wooden rod has a spiral spring of brass wire wound about it and fastened at the lower end to the rod of wood, and at the opposite end to the upper brass ring through which the rod passes.

The rod upon its lower end has the clamp device for holding the stopper. This is composed of three brass strips bent in such a manner as to grip the top of the stopper tightly. The style of stopper used in all the bottles for which this kind of grip was made, is known as the mushroom stopper, and as they differ slightly in shape in different styles and shapes of bottles, require a slightly different bending of the brass grips in order to hold the stopper firmly.

The largest of the three collectors designed has one of its brass grips hinged and snaps down over the stopper, holding it firmly. The other two have rigid grips and depend upon their spring to hold the stopper in place.

The upper end of the wooden rod carrying the clamp for the stopper, has a wire attached to it by means of a ring. The wire passes up the pole, which is clamped to the iron holder. It is by means of this wire that the stopper is raised or lowered in the bottle.

The operation of collecting the sample consists in placing the bottle in the iron holder and securing it by the brass strap around the middle of the bottle. The clamp for the stopper is at the same time properly secured. The apparatus is then lowered into the water to the desired depth by means of the pole, the wire pulled and held, thus raising and holding the stopper until the water has filled the bottle. The wire is then released and the spring upon the wooden rod, before described, forces the stopper back into place quite securely. This does not allow of any more water entering the bottle while being drawn to the surface, even if the bottle is only partially filled with water.

The apparatus is then drawn from the water, the bottle removed and another substituted, and the operation repeated as often as desired.

The strength of the apparatus permits of very rough handling in the exigencies of sample collection, under all sorts and conditions of weather, temperature and travel. Its simple construction makes repair easy, should any accident occur, and insures rapidity in the work of collection, which is an important detail in routine work on an extensive scale. The uniformity of collection secured by this means is extremely desirable where serial and parallel microscopic, bacterial and chemic samples are being taken.

On Wednesday, after the usual announcements and election of new members, a paper on "Pollution of Water Supplies," by Deputy Surgeon General CHARLES SMART of Washington, D. C. This committee had been engaged in perfecting the standard methods for bacteriologic examinations. It was believed that concerted effort would be of more value than individual work. His report being completed he asked that the committee be discharged, which was agreed to.

Dr. ROQUE MOCOUZET, delegate from the Federal District of Mexico, read a paper,

ON THE CITY OF MEXICO AFTER THE DRAINAGE OF THE VALLEY AND THE SANITATION WORK.

The city is 2,265 meters above sea level, and in the 19th degree of latitude. The mean temperature for fifteen years has been: January, 12.9 degrees C.; February, 13.7; March, 15.8; April, 17.7; May, 18.1; June, 17.6; July, 16.9; August, 16.6; September, 16; October, 14.8; November, 13 5; December, 12. The mean atmospheric pressure for fifteen years, 586.37; maximum, 594.19; minimum, 579.80. The primitive city was built on a lake; there was a complete system of canals like Venice. Now it is surrounded by lakes, five in number. The object of the drainage is to give an outlet from the valley to the water which falls within its circumference. The work consists of three parts. A canal which starts from the gate of San Lazars, a length of 47 kilometers and 580 meters; its line follows on the east side of Guadelupe range of hills, then between that range and lake Texcoco, changing a little before it arrives at the 20th kilometer to the north so as to cross lake San Cristobal diagonally, then a part of lake Xaltoc and part of lake Zumpango, of the tunnel close to the town of Zumpango. The tunnel is lined in the upper part with brick. The outer lining is of artificial stone made of Portland cement and sand. The tunnel is calculated for a current of 18 cubic meters per second; twenty-five shafts open with a width of 2 meters and length of 3 meters, at a distance of 400 meters from each other. These ventilate the shaft and aid in the work. The depth of the shaft varies according to the topography of the ground. It will be necessary to construct twenty-three structures to afford passage for the railroad, wagon road and important water courses which require to cross the canal. Five of these by aqueducts to carry rivers; four will be iron bridges for railroads, and the rest are dedicated to the passage of main roads and accommodation roads. The works have two objects, the first to receive the surplus water and sewage of the valley, of the City of Mexico, and carry it away, and the second to control the entire water of the valley, affording an outlet whenever it is found necessary for those waters which might prove prejudicial.

The drainage of the city is the combined water carrying system. He exhibited a sketch to show the plan. The pipes will be laid to carry the water from La Vega canal, that being the source from which the sewers will be flushed, and this will be properly done. There will be no dead ends, as they constitute a focus of infection. The water will be carried to the south end of the 12th Street canal. It will be possible to flush every day all parts of the sewers by sudden rushes of water having with the fall a velocity of one meter per second. In many cases it will be 2 meters per second and even more. Thus will be kept up a constant current of water and with a velocity never below 60 centimeters per second. Up to the present day no city in the world can keep its sewers clean every day. When all is complete, we can receive in the winter, but principally in the summer because then we are more sure of means against the cold, our friends from Canada and the United States if our dear American Public Health Association will consent to come to us, and which contributes to unite the bonds of sympathy with our Republic.

REPORT OF COMMITTEE ON DISINFECTION.

At the last meeting of the American Public Health Association Prof. Franklin C. Robinson of Brunswick, Maine, member of the Maine State Board of Health, was made chairman of a committee on disinfectants and authorized to appoint four associates. He selected Dr. George M. Sternberg, surgeon-general U. S. Army; Dr. Wyatt Johnston, bacteriologist to the Provincial Board of Health, Montreal, Canada; Dr. Alvah H. Doty, health officer, port of New York, and Dr. Eduardo Licéaga, health officer City of Mexico. Owing to the absence in Europe of two members of the committee, Drs. Sternberg and Licéaga, the main consultation has been between the other three members. It was thought best to give special attention this year to gaseous disinfection by formaldehyde, which was brought to the attention of the sanitarians by the chairman and others at the Buffalo meeting. Professor Robinson for the committee reported that the use of formaldehyde had very much increased. Instead of the one apparatus which he presented at Buffalo there are now a half dozen or more. He gave a summary of the matter under the headings: 1. What is formaldehyde? 2. Its proportions. 3. Its preparation. 4. Its manner of use. He said it was a gas, non-poisonous to higher forms of life, but very destructive to bacteria. He said it was made from wood or methyl alcohol by processes of oxidation by which CH_4O becomes CH_2O; that this oxidation was generally brought about by bringing the vapor of wood alcohol mixed with air in contact with hot platinum. He said it was dissolved in water and sold under the name of formalin, formol, etc., and might be obtained from this solution for use as a disinfectant or made directly from wood alcohol. He then went on to describe the various forms of apparatus devised for that purpose and referred to tests with those made by himself and Drs. Doty and Johnston of the committee. He said that the main thing was to have enough of the gas present in a room to ensure thorough disinfection and to let it act for a long time. He gave figures showing that 2.5 grams should be used for one cubic meter of room space. He said he was not prepared yet to pass judgment on all forms of apparatus, but could say that several of them would do this. As to penetration he said that there was not quite as much as the first experiments seemed to show, but still with thorough use he thought it would go where disease germs were likely to. On the whole the report was favorable to its use for the disinfection of rooms.

Prof. SEVERANCE BURRAGE, Department of Sanitary Science, Purdue University, Lafayette, Ind., read a paper on

FUMIGATION EXPERIMENTS WITH FORMALDEHYDE GAS.

It was an account of some experiments at the Newton (Mass.) Hospital with four different generators, the res hich indicate inefficie forms of appara disinfect rooms when operated under conditions to kill all pathogenic bacteria as existing in these rooms. We have several ingenious devices. Without doubt all claims are made with perfect honesty, because so many of the earlier experimenters with this gas gave apparent evidence of its marvelous power to destroy bacteria. Later results indicate too much has been claimed, and these experiments were undertaken on that account. A room, 1,870 cubic feet in dimensions, was subjected to the action of four different generators. All conditions were as much alike in each as possible. Each apparatus was tested twice or even four times. The autoclave with its own operator was tried. The room was closed six hours, and then immediately, as soon as we could enter, the infected cover slips were removed to the laboratory and each placed in agar films in Petri dishes. After five to eight days of incubation at 23 degrees C., growths appeared for all except typhoid fever. All control cultures gave vigorous growths in forty-eight hours. When after seven days' incubation no growth appeared, by taking a platinum needle and scraping over the infected part of the cover slip and inoculating serum tubes with it, growths were obtained except typhoid. The germs were not all killed, but the gas had the effect of greatly inhibiting the growth. He detailed the procedure with each apparatus in turn. From all these results it is impossible to recommend one apparatus over the other. Each did germicidal work better than sulphur as ordinarily used. The principal conclusion is, that the generators did not kill all pathogenic forms as claimed, in a certain space of time. I do believe in formaldehyde, but have no confidence in the class of generators now offered. There are so many conditions as to age and nature of the cultures exposed, the method of exposure, etc., all of which enter into the results, that a large chapter of results must be tabulated to show just what nature will do. We are beginning to understand that the formaldehyde gas will, under proper conditions, kill germs, but in the light of such varying results it is impossible to set a definite formula for room disinfection. However, for all practical work, so far as we know at present, formaldehyde is the best gaseous disinfectant.

Dr. E. A. de Schweinitz, Chief of the Biochemic Division of the United States Department of Agriculture, read a paper on "The Determination of the Amount of Formaldehyde yielded by the Formaldehyde Lamp." There was a great variation as to the amount of gas each lamp gives. Some gave 10 per cent., others 5 to 6 and occasionally 15 per cent. One lamp for one day gave 10 per cent., while the same lamp under exactly the same conditions gave on another day only 1 per cent. When tables were used, 50 per cent. was obtained where 100 had been promised.

Dr. A. W. Reynolds said that in his experiments at Chicago he had tested several lamps; some were not sufficiently rapid, others did better.

Dr. J. McFarland, Philadelphia, said the germs grew as they did when the gas had not been used. He disinfected a room, opened it, and found the germs of diphtheria grew readily. He was disgusted with these lamps.

Dr. Swartz, Secretary of the State Board of Health of Rhode Island, found all that he had tried a failure. We must have a simple, easily operated means. We shall in future find something of use, for he believed we are now on the right track.

Dr. J. F. McShane, Health Officer of Baltimore, detailed some experiments in the laboratory with formaldehyde. He endeavored to determine its action and value on household matters, as blankets, mattresses, etc. He employed the bacilli of typhoid fever and diphtheria. Its penetrating power is poor. He tried the Trillat autoclave; it acted well except as to penetration. Where the bacilli are exposed the gas acted well, but when they were imbedded, as in a mattress, it failed.

Dr. H. D. Pease of the Bacteriological Laboratory of Philadelphia found the spray a failure. The solution must be strong. When the proportion is one of formaldehyde to three of water it will succeed. Having tried both the autoclave and that of the Sanitary Construction Company, he felt that much more experimentation is needed to obtain what we need as a disinfectant. He found that the walls absorb the gas and after three days they would give off the gas freely. Paper is most difficult to penetrate.

Dr. A. W. Suiter of Herkimer, N. Y., read a paper on

THE BARBER SHOP AS A MENACE TO THE PUBLIC HEALTH.

This mode of infection has long escaped the notice of sanitarians. In ancient times cleanliness was provided for because we see the symbol of a brass basin and a striped pole as the sign of the barber. The basin was cut to receive the throat of the customer, so as not to spoil his clothes. At present in France, the police regulations require all instruments to be of metal as far as possible. Thus they can be easily sterilized. All these must be submitted to a heat of 100 C. before and after use; brushes must be placed in boiling water before and after; the hands must be cleansed from one customer to another, the towels must be sterilized, pulverizers are used in place of powder puffs, the hair is disinfected and promptly removed and a chemic solution is prescribed for various purposes. Patients with syphilis have been seen in the shops, with foul ulcers on their faces. One instance occurred to the speaker who encountered a patient just rising from the chair which he was called to fill, so he left and since has permitted his beard to grow, and when compelled to visit a shop he takes along his own apparatus, at the risk of being called a crank. Instances in numbers might be collected where disease has been transmitted in this way. All know it. Every step is dangerous and precautions should be observed. Sponges are not used by a surgeon a second time, yet a barber employs one again and again, a slight squeeze being all it gets from one case to another. Some things the Parisian regulations do not seem to cover, as the alum stick to staunch the blood in case of a cut, and the block of magnesia to dry the skin. Of course some shops are more careful than others. The New York legislature has had before it for years propositions for a law to correct this evil. The organized barbers themselves ask this for their own protection, and to elevate their business. They desire a board of examiners and licensers appointed, so that no one can practice the art unless properly prepared. They would demand a scientific knowledge as to disinfection and general sanitation. This will be pushed at the next session. If enacted, no more can be desired. Why not all occupations licensed? All should be qualified to do the work they set up to do. Horseshoers are now thus qualified in New York. Since the information came from abroad relative to the law in Paris, the medical journals and newspapers comment favorably on it. The people will be quickly educated and the action will be supplemented by favorable sentiment. Let us adopt for our motto, in this respect, the Spanish proverb, "Dicho y hecho," no quicker said than done, and with great promptitude demand an intelligent and unprejudiced inquiry into this fruitful source of disease. If surgeons and dentists are morally and in a negative sense under obligation to disinfect and sterilize their instruments, why not as reasonable to hold the barber responsible; and why not within the province of health boards to protect the public? This Association is striving to regulate the disinfection of cars and demand the stoppage of spitting, and an individual communion cup, and in divers other fields are endeavoring to compel the heedless public to care for themselves; may it not be said that the hygiene of the barber shop far exceeds in importance most of these undertakings?

Mrs. John H. Scribner, Philadelphia, gave in some detail *the work done by the Woman's Health Protective Association* of Philadelphia. Their object was to promote sanitation; to protect their families. They had worked to obtain water filtration and had employed skilled persons to conduct experiments and to visit places where filtration was being done. They had succeeded in getting the Board of Health to place placards in the street cars forbidding spitting in the cars. They had inspected the bake shops and succeeded in obtaining the closing of those which were filthy, and in aiding the bakers themselves to have better and more sanitary working places. They had employed a sanitary expert from abroad to inspect the public schools, and presented a full report to the mayor, so that the proper steps might be taken to have these corrected. In a word, they were determined to keep up the work until they had succeeded in having the entire city in a proper sanitary condition.

Dr. F. W. Wright, Health Officer of New Haven, Conn., read a paper on the

DIAGNOSIS OF SMALLPOX.

This is very important that we may be able early to protect the families from further infection. It must be remembered that the *period of incubation of this disease is fifteen days after* exposure. Occasionally it appears earlier, as in one week after exposure. We have a chill, with subsequent febrile symptoms: intense headache and backache; the temperature is about 103 to 105; this remits on the eruption appearing. The eruption is generally on the third day: may be earlier; or even later to the fifth. Just before we have a redness of the skin, like erythema, when it may be mistaken for measles. At first the eruption is macular, soon it becomes papular; appears first on the face, then on the neck and wrists, next the chests and extend over the whole body. The feet and legs are last. When it becomes papular, we have an induration of the tissues, like shot under the skin, which is characteristic of smallpox. The center of the papule which has been elevated, forms a vesicle; this is never observed under twenty-four hours from the formation of the papule. These vesicles are surrounded by an erythema, and as it progresses, the depression forms making it umbilicated, which gradually becomes more pronounced. The vesicle is filled with a milky serum, it is easily ruptured, and exuding forms a scab. It gains its full size in four or five days. Now the temperature lowers. He then detailed the differential diagnosis between scarlatina, measles, acne, syphiloderma and varicella. In scarlatina, the temperature is high and remains so; there is no remission with the appearance of the eruption; usually there is vomiting; the efflorescence is impalpable to the touch; it appears on the chest and arms first, then on the face; the throat is congested; the headache and backache are not so pronounced; there are no papules nor vesicles. In measles the lungs are irritated from the first, bronchitis; the eruption appears on the face and extends to the rest of the body and more rapidly than in smallpox; the temperature does not fall; the lesions appear in a crescentic form, are pale red, slightly elevated, never papular, or vesicular. If we stretch the skin, it is smooth without the induration beneath as in smallpox. In acne, the eruption is chronic, there is no fever, the eruption is localized, irregular, usually on the face. Syphiloderma may be known by the history, there are small vesicles but rarely, and it is chronic. Varicella is most likely to be confounded with the smallpox, but we are generally sure after forty-eight hours. The eruption is profuse; the invasion starts in a few hours after the fever; the headache and backache are absent or slight and of short duration. We may depend much upon the history as an exposure to either disease; in varicella the pustules are not so full or round, the eruption early empties the elevations, the edges are not thick; also the vesicles soon dry in the center with a small black spot forming.

D. E. Salmon, V. D. M., chief of the Bureau of Animal Industry, Washington, D. C., reported as Chairman of the Committee on Animal Disease and Animal Food. There have been no outbreaks during the past year among the animals of America of unusual extent or manifesting any peculiar characteristics. No exotic diseases have been introduced among our live stock within this period, nor have any new problems arisen, so far as this committee have been able to ascertain, in connection with the protection of the public health from diseases affecting our domestic animals. However, there are numerous questions which have confronted practical sanitarians for years, some of which have been discussed at the previous meetings of this Association and which are still debated, misunderstood and more or less neglected by health authorities. Instead of losing interest as time goes on, some of these questions are becoming more and more urgent. We can only refer to a few subjects which the events of this year have made particularly prominent. Anthrax, tuberculosis, public abattoirs, each in turn was partially discussed; tuberculosis is causing more effort to enable us to effect its stamping out. The problems connected with the control and eradication of this disease among dairy cattle are becoming better understood, and the general plan of procedure which was outlined by your committee at the Chicago meeting is now being largely adopted. The dairymen are being encouraged and influenced in various ways to dispose of their diseased cattle and to replace them with healthy ones. The boards of health of many cities are requiring more rigid inspection of dairies and compliance with prescribed sanitary regulations by those who produce milk for consumption within the territory under their jurisdiction. In a number of the States there are State Boards which are especially charged with the duty of controlling tuberculosis. In some, if not all the New England States, regulations are in force requiring that all dairy cows brought into these States shall have been tested with tuberculin and found free from disease. Similar regulations are soon to be enforced by the authorities of Pennsylvania.

(*To be continued.*)

PRACTICAL NOTES.

Lotion for Anal Pruritus.—Hyposulphite of sodium, 30 grams; phenic acid, 5 grams; glycerin, 20 grams; aq. dest., 450 grams. For external use. Apply compresses moistened with this lotion, frequently, to the anus. — Penzoldt, *Semaine Méd.* October 13.

Formaldehyde in Burns.—A druggist writes to the *Muench. med. Woch.*, that he has discovered formalin to be extremely effective in burns by personal experience. He accidentally poured some boiling culture bouillon over his hands, and applied at once a compress moistened with 10 per cent. formalin. In twenty minutes the pain had quite passed away and when the compress was removed not a trace of the burn was to be seen. The skin was not even red.—*N. Y. med. Woch.*, October.

The Favorable Effect of Injections of Artificial Serum in Cholera Infantum is confirmed by J. Loin of Brussels, who saved three severe cases, six months to three months, with 50 grams of artificial serum injected morning and night, after all other means had failed. Improvement was noticeable after the first or second injection.—*Semaine Méd.*, October 13.

Salicylate of Soda in Serous Pleuritic Effusions.—Poliakov reports five cases in six, cured by 2 to 4 grams a day, after having resisted the effect of repeated punctures. Three were also tuberculous. He finds that it is well tolerated if a little alkaline mineral water is given after each dose or caffein with it in case of weak heart action.—*Sem. Méd.*, October 6.

Tetanus in Children, of Gastro-Intestinal Origin.—1. Salicylate of bismuth, 30 centigrams; benzonaphthol, 15 centigrams; sugar q. s. for one powder. Make twelve similar powders; administer four a day. 2. Bromid of potassium, 3 grams; chloral hydrate, 1 gram; aq. dest., 100 grams; syrup of bitter orange peel, 50 grams; f. s. a. Administer three tablespoonfuls a day. For a child of 2 to 3 years.—E. Tordeus, *Semaine Méd.*, October 13.

Formula for the Administration of Iodoform in Phthisis.—Iodoform is generally well tolerated by phthisics; it relieves the cough, decreases expectoration and has a remarkably soothing effect on the nervous erethism. 1. Iodoform, 2 grams; tannin, 4 grams; for forty powders; two to four powders a day. This formula is for patients with a tendency to diarrhea. If there is constipation, the following is to be preferred: 2. Iodoform, 2 grams; naphthalin, 2 to 4 grams; for forty powders; two to four powders a day.—E. De Renzi, *Sem. Méd.*, September 29.

Electrolysis in Trachoma.—Haun recommends electrolysis after cocainization of the eye, as extremely effective and entirely painless. The patient takes the anode of a galvanic apparatus in his hand and the physician applies the sharp, delicate platinum needle cathode into the granule for five to fifteen seconds. Current 10 to 20 milliamperes. Light cases are cured in from two to three sittings, more severe in five to eight.—*Wien. Med. Presse*, No. 38.

Massage for Postpartum Hemorrhage ex Atonia Uteri—Kumpf reports two cases successfully controlled after all other means had failed, by a sort of massage manipulation which he calls "zitter drückung" or tremolo pressure. He applied his hand to the abdominal wall of the patient at a right angle, between the symphysis and navel, and pressed it back against the spine with a rapid trembling motion of the fingers, afterward applying the same to the rear of the uterus when it became palpable. Contractions of the uterus were soon induced by this mechanical stimulation of the muscles and nerves and the hemorrhage promptly arrested.—*Cbl. f. Gyn.*

Iron Beer.—Jaworski has a beer containing iron, made at the Bukowina brewery, which he has found extremely beneficial in certain cases. The iron is readily absorbed in this form, the taste disguised, while the beverage is nutritious, containing more calories than an equal amount of milk. It is a dark bock beer, composed of 4.07 per cent. alcohol; 8.03 per cent. extracted matters; oxygen 0.21 per cent. and 0.0317 iron in the weaker form; 0.0614 in the stronger beer. The hemoglobin, number of corpuscles, and the weight increased after a few days of its use.—*Therap. Woch.*, September 26.

Diagnostic Significance of Neuralgia in Incipient Aneurysm of the Aorta.—Levachev has observed twenty-nine instances in which cervico occipital neuralgia accompanied aneurysm of the aorta, in 126 cases. In eight this neuralgia was uncomplicated by other nervous troubles. He therefore calls attention to this form of neuralgia as another important indication of beginning aneurysm, in addition to the classic syndrome, and also urges caution in the treatment of neuralgias, as cold douches, mountain climbing, superalimentation, etc., accelerate the evolution of the aneurysm and increase its intensity. He has several times witnessed the fatal termination directly hastened by the treatment instituted for the neuralgia which may be the only symptom at first of the aneurysm.—Moscow Congress.

Iodocresin or "Traumatol."—Dr. W. Schattenmann describes this as a violet-red, amorphous, remarkably fine, bulky, odorless powder, which results from a chemic combination of cresylic acid from coal-tar cresol and iodin, containing about 54 per cent. of the latter. It is insoluble in water, acids, and alcohol, slightly in ether, but readily soluble in chloroform and strong alkalies. Laboratory experiments have demonstrated that it is not poisonous and that it possesses antiseptic properties. It is employed as a powder, crayon, plaster, gauze, vaselin, glycerin and collodion. It may be prepared as a 5 to 10 per cent. traumatol-zinc-paste, 10 per cent. traumatol-lanolin-vaselin, or 10 to 50 per cent. traumatol-chloroform. For venereal ulcers, after preliminary cleansing, it brings about speedy cure. The crayons are useful for the healing of fistulous tracts, dissolving more slowly than those made of iodoform. For genital erosions the collodion is preferred. As a powder, or with chloroform, excellent results have been obtained in syphilitic affections of the mucous membranes. For various operations performed in genito-urinary work, phimosis, buboes, gland extirpations, papillomas, warts, application of the powder, which is covered over with the collodion, is recommended. In addition to its antiseptic properties, its drying and unirritating effects are so marked that its field of usefulness embraces a considerable number of skin diseases. The results obtained on seventy-five patients who were treated by this remedy, used alone, show conclusively that in it we have a valuable addition to our therapeutic resources.—*Therapeutische Monatshefte.*

A New Operation for Malignant Disease of the Testicle.—Stinson (*Medical Record*, Oct. 30, 1897, p. 623) recommends the following mode of procedure in the treatment of malignant disease of the testicle: An incision is made from the external inguinal ring, downward and inward to the beginning of the rhaphe of the scrotum, and following the sulcus between the scrotum and the penis. It is then carried downward and backward, parallel with and external to the rhaphe of the scrotum, and terminates at the scrotoperineal junction. The incision divides the tissues of the scrotum. A second incision, which is slightly curved, is made from the external ring downward, following the sulcus between the scrotum and the thigh and the perineum. It terminates by joining the first incision at the scroto perineal junction. This also divides the layers which form the scrotum. The scrotum, the testicle and its coverings, the median rhaphe, the septum scroti, etc., are as a mass freed from all their attachments, except to the cord, up to the external inguinal ring. Any masses of fat, glands, adhesions, etc., should also be freely removed with these structures. A third incision is made parallel with, and about one-half an inch above, Poupart's ligament, from the external ring to one-half an inch above the internal inguinal ring. It divides the structures superficial to the aponeurosis of the external oblique. The latter is well exposed and divided in the direction of its fibers to about one half an inch above the internal ring. The cut edges are lifted and freed from the structures beneath, so as to expose the cord, etc., up to the internal ring. The cord, etc., are separated from the surroundings, from the external ring to high up within the internal ring, care being taken also to remove freely all mass of fat, glands, adhesions, etc., in the rings and canal. Moderate traction is made on the cord so as to draw it out as far as possible from the internal ring, and it is secured high up within the internal ring with a clamp. Division should be made below it. Any bleeding vessel or vessels are ligated separately with fine catgut. The raw surface of the stump is covered over by bringing together with continuous sutures of catgut the cut edges of the external coat of the cord. When the clamp is removed the sutured edges of the cord at once slip back into the abdomen. The cut edges of the aponeurosis of the external oblique and the pillars of the external inguinal ring are brought together with continuous sutures of chromicized tendon or chromicized catgut. The flap of skin covering the inguinal glands is dissected downward and all of the inguinal glands and fat removed. If the glands are adherent to the skin, the latter is also freely removed. The flap is now replaced and the cut edges of the skin of the groin and the scrotum are united with fine silk sutures, without drainage. A small strip of mercuric chlorid gauze may be inserted for a short distance in the lower angle of the scrotal wound and left in place for a day or so. All hemorrhage should be arrested before the wound is closed.

Analgesic and Antiseptic Uses of Thiol.—This substance, which is a synthetic ichthyol, and has been before the profession about ten years, was first exploited in dermatologic practice, and later had its part in gynecic work, but comparatively little has been heard from it in late years. A German physician, Wirz of Kaisersech, has employed thiol in place of ichthyol, and has had ample opportunity to convince himself of its excellent qualities in a somewhat wide range of cases. As a substitute for ichthyol it seems especially welcome when used on the face, as it is odorless. Patients who could not bear the smell of ichthyol, improved under the use of thiol. In inflamed conditions the analgesic properties of thiol surprised him. It can be used, he says, in inflammations of every description. Infiltrations are resorbed without the formation of pus, making incision unnecessary. In severe carbuncles, after removal of the pus, thiol allayed inflammation when applied around the wound on the infiltrated parts and pain ceased entirely. This was observed in all the inflammatory processes where thiol was used after the removal of the pus. Lymphangitis, even phlegmons caused by panaris, insect bite, and other causes, quickly disappeared under thiol treatment. Inflammation of the face caused by decayed teeth, erysipelatous infiltration of the scalp and face, and severe infiltration of the neck, which took on a serious aspect owing to edema of the glottis, gradually disappeared under constant application of the thiol. In a case of general furunculosis in a child, he directed painting thiol over every furuncle and soon a complete cure resulted. The best results, he says, are obtained with liquid thiol as supplied by the manufacturers, not by that prepared from powdered thiol with the addition of water. In five cases of parametritis he has good results with plugs soaked in thiol and distilled water, equal parts. He also ordered applications of thiol on the abdomen during the night. During the day hot linseed poultices were used. In a severe case of parametritis and perimetritis accompanied by great abdominal pain and high temperature, he had better results with ichthyol, as applications of thiol did not completely allay the pain, while ichthyol induced complete recovery. Cases of otitis externa he has treated with thiol plugs with complete success. No other remedy has rendered him such good service against severe pains in the back after influenza. Patients experienced lasting relief by rubbing thiol over the whole vertebral column. Patients with emphysema, accompanied by marked dyspnea, were relieved as soon as thiol was rubbed on the chest. Pains in the muscles of the thorax ceased, expectoration became easy, and dyspnea and catarrh improved. In pleuritis, as well as croupous pneumonia, thiol was of great service, either alone or together with veratrin and potassium iodid ointment, against pain in the chest. Several patients said that this ointment benefited their condition more than caffein, camphor, hematogen, etc. Wirz has come to the conclusion, therefore, that we possess in thiol an agreeable substitute for ichthyol, odorless, cheap and efficient.—*New York Medical Journal.*

PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:
Per Annum, in Advance $5.00
Foreign Postage 1.75
Single Copies . . . . 10 Cents.

In requesting change of address, give *old* as well as new location.
Subscriptions may begin at any time and be sent to
THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 61 Market Street (Occidental Buildings), Chicago, Illinois.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, 100 Washington St., Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the *Editor*, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street (Occidental Buildings), Chicago.

Original communications are only received with the understanding that they are exclusively contributed to this JOURNAL.

SATURDAY, NOVEMBER 20, 1897.

A DEPARTMENT OF PUBLIC HEALTH.

All the indications point to the establishment at last, in this country, of a National bureau or department of public health. The yellow fever outbreak of the current year has fortuitously and fortunately directed the attention of the people to the urgent necessity for a better organized system of National supervision over the gateways of the seaboard by which epidemic diseases gain admission. The makeshift methods of recent years, utilizing the expedients of a special bureau created for an entirely different purpose, clinical only and not sanitary in its aims, have proved to be ineffective, and the most dreaded of pestilential diseases has actually gained entrance under the very eyes and nose of the much vaunted guardian. Again, the lesson has been taught that the loss of life, the paralysis of business, commercial disaster and disturbed trade relations have footed up to millions, when as many thousands wisely expended by the responsible officers of a National establishment, charged with the protection of the public health—and with nothing else—would have made the former impossible.

Perhaps it is well that the experiment should have been tried of intrusting this work to the Marine-Hospital Service, and though the incidental loss of life and trade ruin are regrettable, the results are what might have been expected and were logically anticipated. These results were not apparent until the management of the Service became what it is today, but the miserable fiasco at Brunswick and the *laisse faire* policy at Ship Island which permitted this year's epidemic, have emphasized in a very unpleasant way not only the decadence of the Service, but how much depends on one man. When that man is fearless, able and active all goes well; when he is indolent, arrogant, tyrannical and playing for social prominence to the disregard of the best interests of his Service, then time shows the failure in no uncertain way. The function of the Marine-Hospital Service is to care for sick and injured masters, mates and sailors of the merchant and revenue marine, as that of the medical department of the United States Navy is to care for sick and injured officers, seamen and marines of the naval service; and while the naval medical officer through his foreign cruising has necessarily a wider practical acquaintance with diseases of other countries, and especially of exotic pestilences, such as yellow fever, in their native habitats, there are manifest reasons why neither the one nor the other—certainly not the Marine-Hospital Service, as at present managed—should be intrusted with the special and specific duties of a National health bureau. If for no other reason, this is inadvisable through the inevitable result of inducing the neglect or perfunctory performance of the legitimate duties for which it was constituted. This is indicated by the last annual report of the head of this bureau—a volume of over eleven hundred pages, of which less than half are devoted to bona fide marine-hospital matters. The medical officers of that service have been diverted from their professional duties at the bedside in attendance upon sick and injured merchant sailors and have been sent to foreign countries, the sum total of their observations having been anticipated by newspaper cable reports and returns from the United States consulates. Had the former been ten times as voluminous they would not have averted the inexcusable calamity, which, as the President of the American Public Health Association (Dr. HORLBECK) so eloquently pointed out, has fallen like a blight upon the southern seaboard States, and made it almost impossible for him to leave his post of duty as Health Officer of the City of Charleston, S. C., to attend the meeting of the Association which had honored him with its presidency on its silver anniversary.

The American Public Health Association "was organized in 1872 by a few public-spirited men impressed with the need of bringing together in one body the ablest sanitarians in the country for the purpose of inaugurating measures for the restriction and prevention of contagious and infectious diseases, and for the diffusion of sanitary knowledge among the people," and happily its twenty-fifth annual meeting at Philadelphia, in October, was signalized by the final report of one of its most important special committees, that on "Public Health Legislation," which under the chairmanship of Dr. HENRY P. WALCOTT, the President of the State Board of Health of Massachusetts, has for years been thoroughly and impartially considering this question of the form of legislation best adapted for the effective National sanitary safeguarding of the country. Dr.

WALCOTT's associates in this work have been sanitary officials of long experience, men charged with the grave responsibilities of the sanitary welfare of their several States and communities, men of such wide reputation that their opinions are of influence outside those localities. That it may be generally known who and what these men are, and their recommendations be better appreciated and accepted without question, their names and offices are here appended: Dr. JAMES N. MCCORMACK, Secretary of the State Board of Health of Kentucky; Dr. JAMES D. PLUNKET, President of the State Board of Health of Tennessee; Dr. HENRY B. BAKER, Secretary of the State Board of Health of Michigan; Dr. SAMUEL R. OLIPHANT, President of the State Board of Health of Louisiana; Dr. BENJAMIN LEE, Secretary of the State Board of Health of Pennsylvania; Dr. U. O. B. WINGATE, Commissioner of Health of Milwaukee, Wis.; Dr. CHARLES O. PROBST, Secretary of the State Board of Health of Ohio; Dr. EMMANUEL P. LACHAPELLE, President of the Provincial Board of Health of Ontario; Dr. GREGORIO MENDIZABAL, the official representative of the State of Vera Cruz, Mexico; Dr. JAMES PATTERSON, Chairman of the Provincial Board of Health of Manitoba; Dr. HENRY D. HOLTON of Brattleboro, Vt., and Dr. DANIEL LEWIS, President of the State Board of Health of New York. Here are thirteen men of prominence, the majority officers of State Boards of Health, who have held their offices for years through political changes of administration, from every quarter of the United States, from Canada and Mexico, from the actual seat of the prevailing epidemic, uniting in the opinion and the earnest recommendation, "that there shall be established a *Department of Public Health*, the duties of which shall be to collect and diffuse information upon matters affecting the public health, including statistics of sickness and mortality in the several States and Territories; the investigation by experimental and other methods of the causes and means of prevention of disease; the collection of information with regard to the prevalence of infections, contagious and epidemic diseases both in this and other countries; also, the causative and curative influences of climate upon the same; the publication of the information thus obtained in a weekly bulletin; the preparation of rules and regulations for securing the best sanitary condition of vessels from foreign ports and for prevention of the introduction of infectious diseases into the United States and their spread from one State into another; that this Department of Public Health shall be under the control and management of a *Commissioner of Public Health*, who shall be appointed by the President by and with the consent of the Senate, who shall hold his office for six years, shall be a regularly educated physician of at least ten years' experience, learned in the practice of medicine, in sanitary science and member of one or more reputable sanitary or medical associations in the United States; and that the Commissioner of Public Health shall semi-annually and at such other time, as he may designate, call to meet in the City of Washington, D. C., an *advisory council* to be composed of the secretary or executive officer of each State and Territorial Board of Health, and an officer learned in the law, detailed by the Attorney-General of the United States from the Department of Justice. A Department of Public Health, controlled and managed by a Commissioner of Public Health, with an advisory council of executive officers of each State and Territorial Board of Health are the essential features of the scheme of law, which was reported to and accepted by the American Public Health Association and ordered to be transmitted to the Congress of the United States as its voice and opinion. This action now unites it with the AMERICAN MEDICAL ASSOCIATION. The elaboration of the scheme may be safely trusted to the National law-makers. A feeble protest against this reference was made at the meeting by the representative of the Marine-Hospital Service on the ground that it was inappropriate for an Association composed in part of Canadian and Mexican members to unite in a proposition concerning only the United States, but the individual protesting was reminded that he himself had endeavored, only a year ago, at Buffalo, to obtain from this same tripartite body the passage of a resolution recommending that the U. S. Marine-Hospital Service should have its powers so enlarged as to constitute *it* the National Board of Health of the United States, and that he had complained in an official report because, as he alleged, a member of the Executive Committee had taken it upon himself to forestall its adoption. The partisan spirit exhibited in this querulous objection is additional reason why a Department of Public Health should be a Commissioner's Bureau independent of any other existing organization, with intimate relations with the State Boards of Health—harmonizing, supplementing and co-operating with them instead of subverting, antagonizing or ignoring them. A health department of this kind is the great immediate National need and the Congress should no longer delay to enact it, in view of the support it has received from State organizations, north and south, and from the great body of representative sanitarians of the country. The authority invested in the General Superintendent of Quarantine of the Dominion of Canada, Dr. MONTIZAMBERT and in the *Consejo Superior de Salubridad* (Superior Council of Health) of the Republic of Mexico, is a practical exemplification of what can be done and ought to be done in the United States. Our neighbors upon the north and south, have the right to expect from us an effective organization with which they can co-operate, and the modest and unobtrusive indorsement given it by their representatives in the American Public Health Association, which boasts that it is truly American in that it embraces in fraternal membership the three great nationalities of North America is welcome and timely.

A NAVAL FIELD HOSPITAL.

A quarter of a century ago this country had a military strength second to none of the armed nations of Europe. It numbered its veteran soldiers not by regiments, but by corps of twenty and twenty-five thousand men, and it was well in the advance in all matters pertaining to warfare, and particularly in the arrangements for the care of the wounded. The ambulance system organized by LETTERMAN and perfected by subsequent experience in the field became a model for the armies of the world. It gave first aid to the wounded, brought them promptly from the fighting line to the field hospitals where all primary operations were performed, and dispatched them to the base of supplies, whence they were transported for further care to the general hospitals. In a word, the Medical Department of the Army was able to deal satisfactorily with all the probabilities of war as then carried on.

But now many medical officers consider that the developments in ordnance which have armed troops with rapid fire, long range and small caliber firearms will render the removal of the wounded from the field an impossibility until the storm of battle has ceased; that an ambulance organization such as operated so successfully during the last two years of our civil war would be swept from the field if it attempted to reach the line of battle during the progress of active hostilities, and that some change must be made in organization and methods if the wounded are to receive first aid and field hospital treatment shortly after they fall. We, however, do not take this view of the subject. Battles are not fought on the level where the long range bullet has sweep. In the wars of the proximate future the first aid stations of the Army Hospital Corps will be found behind the shelter nearest to the line of fire.

But the changes that have taken place in the conditions of naval warfare during this third of a century are infinitely greater than those affecting the land forces. Naval conditions have been changed, not only by improvements in ordnance, but by the efforts of naval architects to meet these changes. Such protection against the improved ordnance of today has been given to the warship and her crew as the knights of old found in their armor against the arrow and pike of the rank and file, and the lance and sword of their knightly opponents. The result has been to transform the ship of the past into a marine engine of war, and in effecting this all the conditions on board have undergone a radical change. Formerly, when a man was injured at his gun, he was carried below and the whole surgical staff was immediately, if necessary, at his service. In army parlance he was brought to the field hospital. The wounded sailor had the advantage in those days, because he received immediately that care which the soldier obtained only after an exhausting ambulance ride from the front to the field hospital.

The battleship of the present day is the equivalent of an army line of battle; and while she may afford, here and there, sheltered places for first aid to the wounded, there is no provision within her armored sides for a field hospital. This revolution in the construction of the battleship necessitates a revolution in the methods of the Navy Medical Department, and our naval medical officers have already given their minds to the accomplishment of this object. At the International Medical Congress at Moscow, Surgeon-General VAN REYPEN presented plans for an ambulance ship to meet the necessities of naval warfare under present conditions; and his proposition has all the more interest, because should this country become involved in war with a foreign power, outside of our neighbors on the north and south, the Navy, not the Army, would have to uphold the flag. His proposition is that with every squadron of battleships there should be an ambulance or hospital-ship, flying the flag of the Geneva Convention, and exposed, therefore, only to accidental injury. His plans for this floating field hospital are excellent. Everything needful appears to have been considered and provided for, and every cubic foot of space to have been utilized to the best advantage. On the upper deck are rooms for convalescent officers and men and for specially serious or isolation cases, with the galley, laundry, wash-room, drying room, lamp room, closets and bath rooms for officers and men, and the offices of the senior medical officer and his executive officer. Dumb waiters go from the galley to the diet kitchens on the decks below. This deck carries four steam launches and four barges, each of the latter capable of bringing off twelve wounded men. The launches and barges are the ambulances of this marine field hospital. Amidship on the berth deck is the operating room. This is lighted from the sides by air ports and from above by a skylight, for the upper deck does not extend over it. On either side of the operating room is an elevator large enough to hold a cot, and run from the upper to the lower deck by electricity. A patient can easily be hoisted from the barge alongside, lowered to the operating room, and carried thence to a cot on the berth deck or lowered to one on the deck below. The transfer is effected by means of an overhead trolley which runs from the operating room and elevators to the distal end of the wards. Below in the engine room, space is provided for an ice machine and cold storage room, a disinfecting chamber, and ample store-rooms for all departments of the ship. The vessel can accommodate comfortably 330 patients, with berthing space for the crew, including its complement of medical officers and nurses or hospital-corps men. To cite from Surgeon-General VAN REYPEN's paper:

"So soon as the action is over the launch should tow its barge alongside a vessel that has been in action, and the wounded should be hoisted out into the barge by means of the apparatus already described; it should then steam with all despatch to the ambulance ship, unload its human freight and speed away again on its mission of humanity. In no other way could wounded men be cared for, or a fighting vessel be more speedily disencumbered and placed again in readiness for battle."

Surgeon-General VAN REYPEN will urge an appropriation for the construction of this ambulance ship, and we trust that he will be as successful in his effort to materialize her as he has been in his work of evolving her from his inner consciousness and ripe experience. We commend his proposition to the Secretary of the Navy and to Congress.

THE ILLINOIS SUPREME COURT DECISION ON EXPERT TESTIMONY.

Two recent occurrences have brought the perennial subject of medical expert testimony again prominently before the profession. One is the decision of the Supreme Court of Illinois placing experts on the same plane, as regards compensation, as witnesses as to facts; and the other, the recent very striking exhibition of expert testimony in a very noted trial for murder. The first of these suggests, more than ever, the need of legislation in this regard and should excite the interest of all professional men who are liable to have their special knowledge, which is their capital, demanded from them without compensation. It is not the medical profession alone that is injured by this judge-made law, and this fact ought to secure for a reasonable proposed statute more general support than might be the case were such a measure demanded only as a prevention of the scandal of a too notable disagreement among doctors with the inevitable popular misconceptions and charges of venality. The failure of previous attempts ought not to be any discouragement to new ones, with the reasons and necessity for such legislation thus reinforced, and it is to be hoped that something may be accomplished in Illinois like what is already achieved, or in fair prospect of being so, in some other States of our Union.

While this decision is for the present final, as giving the legal status of expert testimony in Illinois, it may be questioned whether the State can in future cases derive any very positive advantage from its power to compel those possessing special knowledge to give it on demand without due compensation. No expert will be likely to give his time for consultation without charge and he can not be legally forced to do so, while a prudent counsel will hardly call in the assistance of an expert in a doubtful case without knowing what sort of an opinion is likely to be given. If the State wishes the services of experts hereafter, under this interpretation of the law, in a criminal case, or a private individual or a corporation requires them, they will be likely to have to pay for them, if not for the testimony in court, at least for the needed preliminary consultation, and the same objectionable possibilities exist now as before the promulgation of the Supreme Court decision. If anything, the State is placed rather at a disadvantage by it, for it will probably not be so easy as heretofore to have authorization for the employment of competent experts in questions requiring special knowledge, while private parties or corporations will be untrammeled in this regard.

If the Supreme Court's decision will in any way prevent the unfortunate exhibitions of experts contradicting each other before courts and juries and thus discrediting themselves, their profession and what ought to be an efficient aid to justice, it would be less regrettable, but this is hardly probable. If prosecuting attorneys would always be satisfied with bringing out the actual facts and would never make the conviction of the accused the primary aim, they could call in acknowledged experts without prior consultation and under this decision almost without expense. The real effect, however, will probably be that the defense, having a free hand, will call in its authorities and the State will either have to let their testimony go uncontradicted or employ its counter experts. In civil cases the conditions will remain much as they are at present, and juries and judges will be confused with opposing testimony. That there will be any improvement over the conditions that have existed is certainly very doubtful, and the need of legislation is not less in the interest of the public and the administration of justice than in that of justice to the members of our own and other professions who are called on to appear as witnesses on matters of special knowledge before the courts.

It is to be hoped that the medical profession generally, and all others who are interested in the matter, will combine to use their influence for such legislation as is required. It is needed not only in justice to the experts themselves, but as much or even more than ever in the interest of the administration of justice and to prevent what have been practically scandals in our own and other skilled professions. If the Illinois decision will have for its effect the hastening of this desirable result, it will have rendered indirectly a valuable service in a good cause, though that was not its obvious intention.

DENVER AS A PLACE OF MEETING.

To some extent the success of any particular meeting of the AMERICAN MEDICAL ASSOCIATION depends upon the place at which it is held; yet not upon any one characteristic of the place. To make a notably successful meeting many influences must contribute. Each can help toward the result; yet the result depends more upon the general average of the work done along several lines than upon that lying in any single direction. Take the simple factor of geographic location, particularly with relation to the bulk of the membership of the ASSOCIATION. It would seem very reasonable to suppose that, other things being equal, the meeting held nearest the center of membership would attract the largest number. This is probably generally thought of as the reason why the last meeting was so largely attended. But prior to that the meeting at which there was the largest attendance was held in St. Paul, the point farthest removed from the center of membership of the ASSOCIATION, with the exception of San Francisco, at which any meeting had been held.

It must be borne in mind that while a meeting in the East may have a larger membership to draw upon, a meeting at some western city is certain to draw a larger proportion of possible members within easy reach of it. If, as is the case for next year, the meeting is to be held in the only city of an extensive region in which there is any chance of a meeting being held for many years, it is certain that the physicians of that region will make a much greater effort to attend the meeting than if they could look for its return to some neighboring State within a comparatively short period.

It is also true that much of the success of a meeting depends on the wisdom and energy of the local profession, and on the promptness with which they undertake the work of preparation; and in this respect probably Denver could not be excelled by any city in the country. Already the plans of the Committee on Arrangements are more completely developed, and carried farther into execution than they ever have been before at such an early period. Something of the same disposition to promptly undertake the work laid upon them has been shown by many of the Section officers, with whom also the success of the meeting largely rests; and the list of these officers shows that the arrangement for the Section work for the coming year are in hands as competent as they ever have been in former years.

But, doubtless the most important factor in determining the attendance and success of the meeting of the ASSOCIATION for 1898, will be the special attractions of the place of meeting. While Denver is no farther from the center of the Mississippi Valley than one of our eastern coast cities, those making the trip from the East will be brought together at a few points of departure, Chicago, St. Louis, Kansas City and Omaha; and thence will make the last day's journey, generally the most tiresome part of a long railroad trip, in special trains with the best possible traveling companions, their fellow members of the ASSOCIATION and their families. A long journey made alone may, as we all know, be very tiresome, but a long journey made in company with brother physicians whom we have not seen for a year, or have previously known only by reputation, may be the most delightful and memorable occasion. The specialist can discuss with his brother specialist the minute subdivision of medicine in which they are interested, without interruption, as he could not do at any other time; the medical politician will have the ideal opportunity to exercise his powers in looking after the future welfare of the ASSOCIATION as he sees it; and the general practitioner can live in an atmosphere of sympathy and appreciation completely denied to him during his days of isolated work. The trip is across no deserts like those encountered on the way to San Francisco, but is, at that time of the year, through the most pleasant surroundings and under the most favorable traveling conditions.

It should be remembered that while Denver is not one of the largest of American cities, it has a population greater than that of Newport, Nashville and Atlanta, where recent meetings have been held, added together; and it is particularly well prepared to accommodate large numbers of visitors. Then the professional conscience which does not allow many physicians to take any vacation, unless it serves some distinct purpose of professional improvement, can be entirely satisfied about the Denver trip. While it may not offer the multitudinous clinics of Philadelphia, it will include a study in climatology worth any amount of reading on the subject, a subject which the mass of American physicians greatly need to better understand and appreciate. Many striking observations will be forced upon the attention of even the most careless by a few days residence one mile above sea-level. The general characters of topography and climate of a great section of our country, destined to include many of its most important sanitariums before another generation passes, can be observed there.

The Western hospitality, which seems to culminate in Colorado, will confer not only great personal pleasure, but also great and general professional benefit by the series of excursions it will offer to various parts of Colorado and adjoining States. On some of these a few hours' travel will double or even treble the elevation above sea-level, and will display changes of corresponding extent in the physical features of the country. Probably every physician in the East has sometimes wished for definite, personal knowledge that would enable him to judge of the enthusiastic claims made for Colorado as a health resort; and such knowledge would necessarily improve his judgment with regard to health resorts in general. He will find that the 1898 meeting of the ASSOCIATION in Denver will offer by far the best opportunity for acquiring that desired practical acquaintance with the facts.

mbers in atten[illegible], the real satis-
[illegible] a meeting de-

pends largely upon the local arrangements. This, of course, is not guaranteed by the geographic location of the 1898 meeting; but it is by the energy of the Denver profession and the experience of the city in the entertaining of similar gatherings in the past. Arrangements for very large meetings held in Denver in the last few years indicate that the local arrangements for the AMERICAN MEDICAL ASSOCIATION will be as nearly perfect as it would be possible to make them in any city in the country. Whether the purpose entertained by the Committee of Arrangements, to make the Denver meeting larger than the one recently held in Philadelphia, shall be achieved or not, it is pretty sure to be a very successful meeting, and one that will add largely to the number of members of the ASSOCIATION. Those who, through failure to recognize this, or neglect to make the necessary arrangements to attend it, fail to participate in its advantages, will find their non-attendance a cause for future regret.

CORRESPONDENCE.

Recurrent Diphtheria.

PHILADELPHIA, Nov. 10, 1897.

To the Editor:—I wish to report this case of "Recurrent Diphtheria," as it is one more link that proves that the protective value of antitoxin is only of short duration and further that there is considerable danger in placing patients that are convalescent from diphtheria in close contact with new cases of the same disease. Jennie T., aged 6 years, who gave a history of being sick at home for two days with diphtheritic croup, was admitted to the Municipal Hospital May 21, 1897. Her respirations were so laborious at that time that it was thought advisable to do intubation. After the operation the child became quiet and the respirations were 28 per minute, deep and regular in character. One thousand units of the Philadelphia Board of Health antitoxin was given that evening and the same dose repeated next day. An examination of the throat showed only a mere trace of exudate on the tonsils, although a culture made from her fauces showed the presence of the Klebs-Loeffler bacilli. On the third day after the injection of antitoxin, or the fifth day of the disease, a fine bright scarlatinal rash appeared, extending over the entire body. Her temperature also jumped from 100 to 103 degrees F. The diagnosis of scarlet fever having been made she was removed to the building used for patients suffering with both diseases. The child did nicely and on the eleventh day of the disease, after having worn the tube nine days, she coughed it up at 3 A.M. It was not necessary to reintroduce it, and she was convalescent on June 9, after a period of three weeks' illness. She had been out of bed for nearly two months and had not been sent home as she was still desquamating; when, on July 29, her temperature rose from the normal to 104 degrees F., and both tonsils were found to be thickly covered with a yellowish black exudate. Cultures made from this exudate showed the presence of Klebs Loeffler bacilli. She also started to breathe heavily, which gradually got worse during the next two days. Two or three consultations were held upon the advisability of reintroducing a tube, but upon each occasion it was deemed best to wait. A complication which made this second attack a grave one was severe epistaxis, during the paroxysms of coughing. After the fourth day of her second attack the croupy symptoms began to improve, and intubation was not necessary. The exudate had cleared up rapidly under the local influence of peroxid of hydrogen and internal administration of iron and bichlorid, and she was again convalescent on the seventeenth day of her second attack. She had hardly been out of bed a week and we were about to send her home, when on August 20, she developed her third distinct attack of diphtheria. The exudate extended over and covered the soft and hard palates and was very thick. There was no exudate on the tonsils, uvula or wall of the pharaynx. The culture was positive. She was only confined to bed a week with this last attack, when she made a complete recovery and was discharged. E. L. DRAKE, M.D.

Tea Drinking.

NEW YORK CITY, Nov. 1, 1897.

To the Editor:—Admitting all that is contained in your editorial, as to the evils of tea drinking, let me say that the cup that cheers, contains blessings from a medical standpoint, which one only can see in a country where the tea house has taken the place of the saloon. Japan is a typhoid country and a cholera country; the drinking of hot water is, for the Japanese, a sanitary necessity; but who would ever have consented to indulge in such a beverage even when prescribed by a Budhist priest, if the water had not been pleasantly flavored? Happily for them, tea drinking was introduced in the eighth or ninth century, and they have had time to become perfectly infatuated with it.

Coffee was unknown until introduced by Europeans, in the sixteenth century by the Dutch, from Java. But it never made any headway; nations have their tastes like individuals, about which there can be no dispute. The "Japs" want something every ten minutes, and coffee could not be enjoyed in that way. Mark that in every one of those tiny periods of ten minutes, a fresh cup is brewed. The hot water kettle is forever on the charcoal stove, at the man's or woman's elbow. The individual does not brew an enormous quantum of the delicate beverage, enough to satisfy father, mother, children and the stranger within the gate; he culls from his cannister a simple pinch of tea leaves, drops it into his diminutive cup (holding perhaps an ounce) and pours his boiling water on it. As soon as the water shows color he drinks it. He may drink a quart or two in a day, for wherever he goes, visiting or shopping, the cheering cup is surely offered to him. It has been observed, with shocked amazement by foreigners in Japan, that a native will, without the least embarrassment, excuse himself, even to the ladies, and ask for the water closet. The tea leaves him no rest.

Of course a penalty has to be paid for these excesses, rather two penalties. The high class, who drink the finer sorts, suffer from nervous disorders; the lower class, to whom the coarser brands are left, are subject to those dyspeptic troubles deplored in your article.

Tea drinking has not only kept down typhoid fever and cholera contagion, it has also obviated alcoholic intemperance. There is no saloon in Japan, except the tea saloon. Perhaps the absence of pauperism is to be ascribed to that. It is to me a puzzling question whether tea guzzling would not do some good even in this white country, in spite of thein, caffein and tannin. ALBERT S. ASHMEAD, M.D.

Treatment of Snake Bite.

SIERRA MOJADA, MEXICO, Nov. 8, 1897.

To the Editor:—In the JOURNAL of October 30 J. G. Tuten, M.D., Jesup, Ga., gives a lengthy description of the treatment of a snake bite. The doctor's patient was long suffering and that he was kind is evident from the fact that he didn't change doctors. The grave symptoms, horrible suffering and extensive sloughing were the result of the absurd treatment and not of the poison of the snake bite. The bite of the rattlesnake does sometimes prove fatal, but if treated properly, very rarely. The tourniquet or ligation of an extremity is always bad. A word as to my method of treatment, and I have treated more than two dozen in the last ten years with no deaths. If there is very recent scarification and sucking of the wound, then I make free incisions and immerse the part in warm water to promote bleeding; then apply gauze wrung out of hot antiseptic solutions on absorbent cotton with moist heat to all the swollen portion; whisky frequently repeated in stimulating doses, no more. Digitalis is sometimes necessary and is very good, when indicated. Free catharsis is produced with calomel and milk diet, or other nutritious articles of easy digestion ordered. W. Q. Marsh, M.D.

A Question of Medical Ethics.

Atlantic, Iowa, Nov. 9, 1897.

To the Editor:—The great medical charities of this country are a credit to the profession and others whose gratuitous services make their existence possible; and no medical man will deny that the good done by these institutions is well-nigh incalculable.

That abuses of the system have been and are constantly being practiced no one will deny, and the periodic complaints from those physicians who live near the large dispensaries are familiar to all who read the current medical journals.

That abuses of medical charities had begun to extend into the country was not suspected by me until lately, when there fell under my observation something that I think needs attention from that portion of the profession who believe that quackish methods are not admissible even in the practice of those who are wont to assume that they are exempt from the operation of the time-honored "Code of Ethics." A certain sanitarium whose advertisement can be seen in nearly all the leading medical journals is, as is well known, under the control and guidance of a certain religious organization, and has as its chief medical officer a man who is a prolific writer, and is always prominent on the floor at the meetings of the American Medical Association. I find that it is the universal habit of the ministers who preach the gospel as viewed by this sect, to go among the people in their vicinity and solicit cases for this institution, without regard to the circumstances; this is done on the ostensible ground that trained nursing and superior medical skill can be obtained at a far less rate than can be obtained at home. One case that came under observation was that of a man suffering from a large appendiceal abscess, who performed a journey on the cars of over 650 miles and was operated on, making a slow recovery from an intestinal fistula; that he did not rupture the abscess *en route* and die of peritonitis is due wholly to good luck. Two cases have recently come under my observation in which this same minister induced two women to discharge their local physician and repair to this sanitarium for the purpose of having celiotomy done. The chief of the staff of this institution must know of these facts, for he requires the ministers to have the patients ask their attending physicians for a written "diagnosis" of the case before agreeing to admit them; the other binding clause of the bargain is that they pay if they can, and if unable to do this, promise to do so when they can. Patients who are abundantly able to pay are thus taken and worthy men robbed of cases from which they could collect a legitimate fee, that the sanitarium may get the hospital fee, arrangement for which must always be made. If this is legitimate practice of medicine, the country practitioners want to know it; and if it is not, let us insist that those who are a party to this sort of thing take their place among the itinerants, and not contaminate our medical meetings with their presence. Yours very fraternally,

Frank W. Porterfield, M.D.

National Medical Education.

Boise, Idaho, Nov. 10, 1897.

To the Editor:—In the article on "National Medical Education" by Dr. Greeley in the Journal, October 23, someone is quoted as stating that "the effort of the State Society to establish a State Board of Examiners was defeated by the quacks, but this winter will see such a bill passed"; this in reference to Idaho.

I am proud to say that the above quoted prediction was verified on March 12, 1897, and Idaho now has in operation a mixed board of medical examiners, and the act under which this board is operating provides that the person wishing to take up practice in Idaho must possess diploma from a recognized school, and pass a satisfactory examination before this board. This provision is met by applicants receiving a marking of at least 75 per cent. on all questions asked. The examination is written, and comprises papers on some fourteen subjects. At the first examination held by the board 50 per cent. failed to pass. This Act of March 12, 1897, is now being attacked in the courts by some who have felt the weight of its provisions, as administered by this Board, and time alone will determine whether the Act as passed by the legislature of 1896-97, will pass muster in the supreme court of the State.

Very truly yours, C. L. Sweet, M.D.,
Secretary Idaho State Board Medical Examiners.

Department of Public Health Bill.

Chicago, Nov. 10, 1897.

To the Editor:—Will you kindly oblige the undersigned by mailing to my address not less than twenty copies of the Bill looking to the establishment of a Department of Public Health, as I propose to do some *more* missionary work in that direction among our National legislators ere the convening of Congress next month.

The editorial on this subject in the November 6 issue of our Journal was most timely, and should elicit renewed interest in the profession everywhere.

I trust the enterprising physicians of the United States, to the number of 100,000, will awake to the necessities of this important piece of legislation, and arouse their Representatives and Senators in both Houses of our Government to renew their interest in this matter for the welfare of this Government and for all her peoples. Very sincerely yours,

Liston H. Montgomery, M.D.

A member from Illinois on the Special Committee of the American Medical Association on Department of Public Health.

Edema Universalis?

Chicago, Nov. 13, 1897.

To the Editor:—Med. Dr. Gustavus M. Blech desires to know, in the last number of the Journal, whether a certain case observed by him is justly called by him "edema universalis?" Certainly not. It should be called "edema universa*le*." The meager description offered allows no definite diagnosis, but it seems probable that the edema was due to "sclerema neonatorum." Joseph Zeisler, M.D.

License in Germany?

Rolla, Mo., Nov. 13, 1897.

To the Editor:—Will some reader of the Journal give information concerning the laws of Germany in regard to American physicians who wish to locate and practice there? What is required of a graduate of American medical schools, in order to obtain license to practice? A Reader of the Journal.

Let us have a Department of Public Health!

BOOK NOTICES.

Traumatic Injuries of the Brain and its Membranes; With a special study of pistol shot wounds of the head in their medicolegal and surgical relations. By CHARLES PHELPS, M.D., with forty-nine illustrations; pages 582. D. Appleton & Co., New York: 1897.

This work is a concise and systematic treatise on that division of brain surgery arising from injuries of the brain through external violence, and has been based almost exclusively on the observation of five hundred consecutive cases of recent occurrence. Although the cases were so numerous, it seems they were incomplete only in the illustration of secondary pyogenic infection, which is naturally a tribute to the skill of the surgeons in charge of the cases, inasmuch as they were kept from infection. This clinical deficiency has been supplied by excerpts from Macewen's work on inflammations of the membranes of the brain and spinal cord, with the permission of that gentleman. We have no hesitation in saying that it is the most complete work on this division of brain surgery which has yet appeared in America. We therefore extremely regret to see that the book has been published without an index. Although the table of contents is unusually full, yet it is a great defect, and one which in these days of cataloguing, indexing and tabulation, should not have been permitted. The paper is excellent; the illustrations are fine, and the work will remain for a long time a very valuable book of reference on this subject.

Lectures on the Malarial Fevers. By WILLIAM S. THAYER, M.D. Pages 326. New York: D. Appleton & Co. 1897.

This work consists of nine lectures with three illustrative charts. The lectures cover the ground of the history of the development of our knowledge concerning the pathogenic agent of the malarial fevers; methods of examination of the blood; description of the hemocytozoa of malaria; general conditions under which malarial fevers prevail; clinical description; masked malarial infections; conditions of the urine in malarial fever; sequelæ and complications; morbid anatomy; general pathology, diagnosis, prognosis, treatment and prophylaxis.

The author, speaking from experimental evidence, decides against the possibility of infection by drinking water, and as a means of prophylaxis recommends that one should avoid exposure at night and damp or marshy districts. People should choose sleeping apartments in an upper story of the house and always sleep under a mosquito net, and that small doses of quinin taken daily are very efficacious. These lectures are extremely valuable for reference.

Incompatibilities in Prescription. For Students in Pharmacy and Medicine and Practicing Pharmacists and Physicians. By EDSEL A. RUDDIMAN, PH.M., M.D. First Edition, pp. 264. New York: John Wiley & Sons. London: Shipman & Hall, Limited. 1897. Price $2.

Every druggist knows that he is sadly in need of the knowledge contained in works of this kind, and this volume supplies the information needed concisely and thoroughly. The articles are arranged alphabetically, which renders an index on incompatibles less necessary than in most works. They are here given without comment other than that necessary to properly classify and arrange them. This is one of the most important divisions of chemistry, and no student or young practitioner can very well afford to be without this book.

A Practical Treatise on Sexual Disorders of the Male and Female. By ROBERT W. TAYLOR, A.M., M.D.; with seventy-three illustrations and eight plates in color and monotone. Lea Bros. and Co. New York and Philadelphia. 1897. Pages 451.

The aim of the author of this volume, says Dr. Taylor, "has been to portray the various forms of sexual disorders in the male on the basis of advanced knowledge of the anatomy, physiology and pathology of the various portions of the sexual sphere." The author points out that the failure of antecedent treatises on the subject to furnish practical information, has been due to the fact that the mode of certain neuroses and the symptoms of sexual debility, termed functional disturbances, so over-mastered the minds of writers that some "unimportant points" were unduly magnified or wrongly presented.

The great experience of Dr. Taylor in the treatment of affections of this nature, and his experience as an author, make his opinions of immense value; hence we cannot too highly commend to the general practicing physician and surgeon the perusal of this work and its addition to the library.

A Text-Book of the Practice of Medicine. By J. M. ANDERS, M.D., Ph.D., LL.D. Illustrated. Philadelphia: W. B. Saunders. 1898. Price, $5.50 net; pages 1287.

This work is thoroughly modern in all respects. The author has given preference to modern orthography and terminology, and wherever dosage is stated has used the metric equivalents. It is, however, not a mere translation, but in all instances in which this would involve an important difference in quantity the exact decimal figures are given. Current medical literature has been utilized in this contribution.

The book covers infectious diseases and constitutional diseases; diseases of the blood and ductless glands; diseases of the respiratory system; diseases of the urinary system; diseases of the nervous system; diseases of muscles; the intoxications, and the animal parasitic diseases.

Special attention has been given to diagnosis; and the work is to be commended. An unusually full index completes the volume.

True to Themselves; A Psychological Study. By ALEXANDER J. C. SKENE, M.D., LL.D. F. T. Neeley, Publisher. London and New York: 1897.

This novel by Dr. Skene is so extremely advanced in telepathy and certain phases of sociology, that it is difficult to review it from that standpoint, without criticism which we would very much dislike to make; but from the standpoint of a story it is romantic, entertaining and interesting. Dr. Skene has written a remarkable novel, and has introduced some original characters into the book, as Dr. Douglas, one who followed the usual career of those whom the gods love; that is to say, he died young. He was so wonderfully good as to constitute an ideal character. The female characters in the book are women of exceptional purity, but some of them, especially Mrs. St. Clair, would be an almost impossible reality. However, in the favorite dialect of Francie, it was a braw thocht that mad them.

Therapeutics, its Principles and Practice; a Work on Medical Agencies, Drugs and Poisons, with Especial Reference to the Relations Between Physiology and Clinical Medicine. By H. C. WOOD, M.D., LL.D. Tenth Edition; thoroughly revised. Philadelphia: J. B. Lippincott Company. 1897 Pages 1033.

The fact that Professor Wood's book has reached its tenth edition is sufficient evidence of its popularity and of the high appreciation of the physician and students who have depended upon it for their knowledge of therapeutics. It is to be regretted that this edition still retains the old system of weights and measures. The large number of new remedies that have been introduced since the last revision of the Pharmacopeia and the toxins and antitoxins have made it necessary that every work on therapeutics, aiming to be at all complete, should contain an account of them. These have been added in this edition, so that the work has been brought down to the latest date possible.

Transactions of the Chicago Pathological Society. December, 1896 to April, 1897. Volume II, American Medical Association Press.

This volume of Transactions of this flourishing Society is an improvement on its predecessor, not only in style and arrangement, but in the material. The papers that are contained in the volume have been published in this JOURNAL from time to time, and most of the Journal readers are familiar with them; but they are here together and preserved in permanent form of Transactions and collectively represent a very high plane of medical literature. Pathologic cases are always instructive, and the observer of today may turn to his Monroe, his Andral, his Rokitansky and Gross for descriptions, of the macroscopic lesions as seen by these keen observers and recorded according to the fashion of the time. But the appearances themselves never grow old, and we may indeed hope that these pathologic reports of today may take their place in the library as works of reference scarcely inferior to any of their class.

Text-Book of Medical and Surgical Gynecology. For the Use of Students and Practitioners. By R. W. Garrett, M.A., M.D. Containing over 100 illustrations. Kingston, Ontario, 1897. J. A. Carveth and Company, Medical Publishers, Toronto, Canada. Pages 419.

This is a condensed manual of gynecology, having few sins of commission and few of omission. It contains the essentials of gynecology as now taught and practiced. The size of the work forbids extended quotations or lengthy citations, but the student will find it fairly up to date.

SOCIETY NEWS.

Chicago Pathological Society.—The annual address before the Chicago Pathological Society, December 3, will be delivered by George M. Sternberg, Surgeon-General of the United States Army. The subject of the address will be "Yellow Fever; Its Etiology and Pathology."

Southern Surgical and Gynecological Association.—The following officers have been elected for the ensuing year: President, Dr. Richard Douglas, Nashville, Tenn.; Vice-Presidents, Dr. H. H. Mudd, St. Louis, Mo., and Dr. Jas. A. Goggans, Alexander City, Ala.; Secretary, Dr. W. E. B. Davis, Birmingham, Ala.; Treasurer, Dr. A. M. Cartledge, Louisville, Ky. Place of meeting, Memphis, Tenn.; on the second Tuesday in November, 1898.

The Oldest Medical Society in Illinois.—The Æsculapian Society of the Wabash Valley celebrated its fiftieth anniversary at Paris, Ill., Oct. 28, 1897. There were about seventy-five members of the profession in attendance. In the evening the local physicians gave a banquet, at which there was good music, appropriate speeches, and a good time generally. The Society is in a most flourishing condition. The Æsculapian was organized in 1846, and hence has been in existence fifty-one years, but as it did not receive its charter until 1847, the year 1897 was celebrated as the fiftieth anniversary.

NECROLOGY.

Dr. Thomas W. Evans, the famous American dentist, died suddenly of angina pectoris, November 14. Dr. Evans was born in Philadelphia about seventy-five years ago, and went to Paris in 1846, where he remained the friend of the United States during the Civil War, buying American securities when they dropped to very low points, thus backing up his statement that the Confederacy could not win. Dr. Evans was practically the first person to introduce gold filling for teeth into Europe. Since his advent in the French capital, Dr. Evans had attended to the teeth of most of the crowned heads of Europe, to say nothing of almost innumerable members of the royal families, excepting Queen Victoria and the Sultan of Turkey. At the time of his death he occupied the office of dentist to the royal families of England, Holland, Germany, Austria, Belgium and Russia, besides being the attendant of the majority of the most prominent families of the continent. During the course of his life he received innumerable orders and other decorations from foreign potentates. He was an intimate friend of Napoleon III., and at the time of the Franco-Prussian war organized the National Ambulance Corps. When the French communists were seeking for the Empress Eugenie to destroy her, he disguised her as a maid and aided her in her escape. In Germany he is known and loved for the services he rendered the ill-starred German Emperor Frederick when, as the Crown Prince, he was battling for his life against the inroads of the disease to which he finally succumbed. The Prince was at San Remo dangerously ill with the disease of the throat which baffled the skill of the most learned scientists of all Europe, when Dr. Evans was called into consultation. Sir Morrel Mackenzie, the eminent English surgeon, and Dr. Bergmann of Berlin, were in charge of the distinguished patient. They decided on an operation to remove the growth and he was present. At this time the old Emperor William was also lying sick unto death. It was known that his death was a matter of only a few days' time, and also that unless the cancer could be removed from the throat of the Prince he would precede his father to the grave. A tracheotomy was performed and the bleeding which followed could not be stopped by all the efforts of the physicians in attendance. Dr. Evans hurried to a silversmith's shop, and with his own hands constructed a silver tube, which was fitted into the wound and stopped the bleeding. Twenty-four hours later Emperor William died and Frederick lived for thirty days as Emperor of Germany. Dr. Evans is estimated to be worth $30,000,000. He left no children. He founded the Home for Young American Women in Paris, which has proved a veritable godsend to many an American girl studying art in Paris.

James G. Sloan, M.D., Jefferson 1862 and Georgetown Medical College, D. C., 1869, died at Monongahela City, Pa., November 2, aged 56 years. He served in the ranks throughout the civil war, having enlisted as a private in a Pennsylvania regiment immediately after his first graduation. Afterward he was four years in the land office bureau of the Department of the Interior, Washington, and in 1896 became a member of the Pennsylvania Legislature, in which position he remained until his death.

James Carey Thomas, M.D., University of Maryland, 1854, for many years a trustee of the Johns Hopkins University, author of several medical works and well known as a lecturer, died in Baltimore on the evening of November 9. His wife, who died several years ago, joined him in his philanthropic works; both were earnest workers in the Society of Friends and their daughter, one of the immediate survivors, is president of Bryn Mawr College, Philadelphia, as well as a trustee of Cornell University. Dr. Thomas was 64 years old.

George O. Butler, M.D., Cleveland, Ohio, of heart trouble, November 4, aged 64 years. Dr. Butler was graduated from Western Reserve Medical College in 1854. He practiced with his preceptor for one year, and then in West Virginia for a somewhat longer period, then in Cleveland. In 1862 he was appointed surgeon of the One Hundred and Third Ohio Volunteer Infantry. After the war he resumed his practice in Cleveland, and near Rock's Corners. Since 1872 he has been a member of the Northern Ohio Medical Society, and in 1868 was one of the organizers of the old Cleveland Academy of Medicine. In 1885 he was appointed a member of the United States Pension Examining Board of Surgeons, and was for three years the secretary of the board.

S. F. Forbes, M.D., of Toledo, Ohio, died at Sorocco, N. M. ——Dr. Hughes, late of Carmarthen, father of the Rev. Hugh Price Hughes of London, died at Barry, November 3.

PUBLIC HEALTH.

Bubonic Plague Raging in Many Bombay Districts.—The bubonic plague is raging in the districts of Poona, Sholapur and Surat. It has also appeared at Kotri, near Karachi, in the Sinde district and at Jand-Kawal, in the Julundun district. Near Hardwar a colony of monkeys has been attacked by the disease. The local authorities are trapping and isolating the diseased animals.

Vital Statistics of New Jersey.—The State Bureau of Vital Statistics of New Jersey has given out advance sheets from
